Dolutegravir has low potential to cause clinically significant drug-drug interactions. Its capacity to inhibit the renal organic cation transporter OCT2 likely explains its effects to double concentrations of metformin. Dolutegravir is susceptible to decreases in plasma concentrations caused by inducers of drug-metabolizing enzymes and should not be coadministered with etravirine, nevirapine, or St. John’s wort. For some enzyme inducers such as rifampin, efavirenz, and ritonavir-boosted HIV PIs, the dolutegravir dose can be increased from 50 mg once daily to 50 mg twice daily to counter this effect (Dooley et al., 2013). Similar to other HIV integrase inhibitors, dolutegravir should be taken 2 h before or 6 h after cation-containing antacids or laxatives, sucralfate, or oral supplements containing Fe2+ or Ca2+. However, supplements containing Fe2+ or Ca2+ can be taken at the same time as dolutegravir if given with food (Osterholzer and Goldman, 2014). Lami-vudine is no longer considered adequate suppressive therapy for chronic HBV infection; therefore, the coformulation of dolutegravir with abacavir and lamivudine should not be considered adequate treatment of HBV in coinfected patients (see Chapter 63). If a patient is coinfected with HBV or becomes infected during treatment, abrupt discontinuation of dolutegravir/abacavir/lamivudine may result in rebound HBV replication and acute liver damage. The dolutegravir/abacavir/lamivudine combination should not be given to patients who are known to carry the HLA-B*5701 allele because of the risk of abacavir hypersensitivity.

### Future Treatment Guidelines

Several expert panels issue periodic recommendations for use of antiretroviral drugs for treatment-naive and treatment-experienced adults and children. In the U.S., the Panel on Clinical Practices for Treatment of HIV Infection issues updated guidelines approximately every 6 months; their most recent guidelines can be accessed online (http://www.aidsinfo.nih.gov/Guidelines) (Department of Health and Human Services, 2016).

Treatment recommendations compare various regimens currently available for treatment-naive patients and also address when to change therapy in individuals who are failing their current regimen. The specific drugs recommended may change as new choices become available and clinical research data accumulate. Selection of drugs in the developed world will be driven by genotypic and phenotypic resistance testing. However, future treatment guidelines will likely continue to be driven by three principles:

- Use of combination therapy to prevent the emergence of resistant virus
- Emphasis on regimen convenience, tolerability, and adherence in order to chronically suppress HIV replication
- Realization of the need for lifelong treatment under most circumstances

Treatment guidelines are not sufficient to dictate all aspects of patient management. Prescribers of antiretroviral therapy must maintain a comprehensive and current fund of knowledge regarding this disease and its pharmacotherapy. Because the treatment of HIV infection is a long-lived and complex affair, and because mistakes can have dire and irreversible consequences for the patient, the prescribing of these drugs should be limited to those with specialized training. Prescribers should also be aware that several additional antiretroviral agents are in advanced clinical development and could alter treatment possibilities. These include the NNRTI doravirine and the integrase strand transfer inhibitor (InSTI), cabotegravir and bictegravir (Flexner and Saag, 2013). Experimentally, cabotegravir has been formulated in nanoparticles having a $t_1/2$ of 3 weeks, raising the possibility of a sustained-release formulation that would deliver the drug for several months.

Pharmacotherapy of Neoplastic Disease

Chapter 65. General Principles in the Pharmacotherapy of Cancer / 1161
Chapter 66. Cytotoxic Drugs / 1167
Chapter 67. Pathway-Targeted Therapies: Monoclonal Antibodies, Protein Kinase Inhibitors, and Various Small Molecules / 1203
Chapter 68. Hormones and Related Agents in the Therapy of Cancer / 1237
Cancer pharmacology has changed dramatically during the recent past with the improved understanding of cancer biology and an ever-expanding set of newly developed drugs that target vulnerabilities in individual cancers. Effective early treatments have been developed for some fatal malignancies, including testicular cancer, lymphomas, and leukemia. Also, adjuvant chemotherapy and hormonal therapy can extend overall survival and prevent disease recurrence following surgical resection of localized breast, colorectal, and lung cancers. Chemotherapy is also employed as part of the multimodal treatment of locally advanced head and neck, breast, lung, and esophageal cancers; soft-tissue sarcomas; and pediatric solid tumors, thereby allowing for surgery that is more limited with favorable outcomes (Chabner and Roberts, 2005). In the past 5 years, the ability to harness the power of the immune system in the treatment of cancer has brought about a paradigm shift whereby some of the most feared diseases, such as melanoma and lung cancer and even late-stage metastatic disease, can be eradicated. For some cancers, response rates are surprisingly high: 87% in Hodgkin lymphoma even in heavily pretreated patients (Ansell et al., 2015), and 50% in patients with metastatic melanoma treated with combinations of PD-1 and CTLA4 immune checkpoint antibodies. Immune checkpoint inhibitors are currently approved for the treatment of bladder cancer, Hodgkin lymphoma, kidney cancer, lung cancer, and melanoma; more approvals are anticipated in the near future based on several hundred ongoing clinical trials.

Despite these major therapeutic successes, few categories of medication have a narrower therapeutic index and greater potential for causing harmful effects than anticancer drugs. A thorough understanding of their mechanisms of action, including clinical pharmacokinetics, drug interactions, and adverse effects, is essential for their safe and effective use. Anticancer drugs are quite varied in structure and mechanism of action. The group includes alkylating agents; antimetabolite analogues of folic acid, pyrimidine, and purine; natural products; hormones and hormone antagonists; and a variety of small-molecule drugs and antibodies directed at specific molecular targets, such as extracellular receptors, intracellular kinases, or the checkpoints of immune surveillance. Figure 65–1 depicts the cellular targets of these drugs, and Chapters 66–68 provide information on the different classes of drugs.

Anticancer drugs are increasingly used in a variety of nonmalignant diseases and have become treatment standards, for example, for autoimmune diseases (rituximab); rheumatoid arthritis (methotrexate and cyclophosphamide); Crohn disease (6-mercaptopurine); organ transplantation (methotrexate and azathioprine); sickle cell anemia (hydroxyurea); psoriasis (methotrexate); and wet macular degeneration (ranibizumab and aflibercept).

**The Cell Cycle**

An understanding of the cell cycle is essential for the rational use of anticancer drugs (Figure 65–2). Many cytotoxic agents act by damaging DNA. Their toxicity is greatest during S phase, the DNA synthetic phase of the cell cycle. Other agents, such as the vinca alkaloids and taxanes, block the formation of a functional mitotic spindle in the M phase. These agents are most effective on cells entering mitosis, the most vulnerable phase of the cell cycle. Accordingly, human cancers most susceptible to chemotherapy are those having a high percentage of proliferating cells. Normal tissues that proliferate rapidly (bone marrow, hair follicles, and intestinal epithelium) are thus also susceptible to damage from cytotoxic drugs. Slowly growing tumors with a small growth fraction (e.g., carcinomas of the colon or NSCLC) are less responsive to cell cycle-specific drugs.

Although cells from different tumors display differences in the duration of their transit through the cell cycle and in the fraction of cells in active proliferation, all cells display a similar pattern of cell cycle progression (Figure 65–2):

- **A phase that precedes DNA synthesis (G1)**
- **A DNA synthesis phase (S)**
- **An interval following the termination of DNA synthesis (G2)**
- **The mitotic phase (M) in which the cell, containing a double complement of DNA, divides into two daughter G0 cells**
- **A probability of moving into a quiescent state (G0) and failing to move forward for long periods of time**

At each transition point in the cell cycle, specific proteins, such as p53 and chk-1 and 2, monitor the integrity of DNA and, on detection of DNA damage, may initiate DNA repair processes or, in the presence of massive damage, direct cells down a pathway of cell death (apoptosis). Some anticancer drugs act at specific phases in the cell cycle, mainly at the S and M phases; other drugs are cytotoxic at any point in the cell cycle and are termed **cell cycle phase nonspecific**.

Each transition point in the cell cycle requires the activation of specific CDKs, which, in their active forms, couple with corresponding regulatory proteins called cyclins. The proliferative impact of CDKs is, in turn, dampened by inhibitory proteins such as p16INK4A, a tumor suppressor named for its molecular mass (protein of 16 kDa) and inhibition of CDK4. Tumor cells often exhibit changes in cell cycle regulation that lead to relentless proliferation (e.g., mutations or loss of p16INK4A or of other inhibitory components of the so-called retinoblastoma pathway, enhanced cyclin or enhanced CDK activity).
The CDK family consists of over 20 serine/threonine protein kinases that have been amongst the first pathway targets pursued for the treatment of cancer. However, different tissue selectivities and distinct cell cycle–specific activity periods of the various CDKs provide a challenge for the development of CDK inhibitors. CDK4/6 have become attractive targets because they control cell cycle progression from the G1 to the S phase. Interaction of cyclin D with CDK4/6 enhances phosphorylation and inactivation of the retinoblastoma (Rb) protein, followed by the transcription of factors that control transition into the S phase. CDK4/6 inhibition will thus cause a G1 arrest in susceptible cells that utilize this pathway. The CDK4/6 inhibitor palbociclib was recently approved for the treatment of breast cancer (see Chapter 67).

Because of the central importance of DNA to the identity and functionality of a cell, elaborate mechanisms (“cell cycle checkpoints”) have evolved to monitor DNA integrity. If a cell possesses normal checkpoint function, drug-induced DNA damage will activate apoptosis when the cell reaches the G1/S or G2/M boundary. However, if the p53 gene product or other checkpoint proteins are mutated or absent or the checkpoint function fails, damaged cells will not divert to the apoptotic pathway but will proceed through the S phase and mitosis. The cell progeny will then emerge as a mutated and potentially drug-resistant subpopulation (see Figure 65–3A).

Cancer Evolution and Drug Discovery

The rapidly expanding knowledge of cancer biology and the ability to analyze cancer genome alterations in thousands of patient samples have led to a better understanding of the molecular evolution of cancer and the discovery of cancer-specific drug targets: growth factor receptors, intracellular signaling pathways, epigenetic processes, tumor vascularity, DNA repair defects, cell death pathways, and immune escape mechanisms (Hanahan and Weinberg, 2011). Human malignancies are a highly diverse...
Clinically detectable cancer lesions represent approximately 1 g of tumor tissue or 10^6 cells and can contain a multitude of subpopulations and a wide variety of genetic alterations (see legend of Figure 65–3). The dynamic evolution of individual cancer genomes and the implications for the development of therapies was established from the analyses of specimens from diverse cancers (Yates and Campbell, 2012). This dynamic was exemplified in a detailed analysis of a series of multiple parallel biopsies from different sites in patients with metastatic melanoma during treatment with inhibitors of BRAF. The genomic analysis of the biopsies revealed complex and distinct evolutionary branching architectures due to the selection of drug-resistant subpopulations during treatment (Shi et al., 2014).

Nevertheless, in many tumors, proliferation and survival of the majority of subpopulations depends on a shared (ancestral) constitutive activity of a single growth factor pathway, or so-called oncogene addiction. Inhibition of that pathway leads to cell death of the sensitive populations. Thus, imatinib attacks the unique and specific bcr-abl translocation in chronic myelocytic leukemia. Imatinib also inhibits c-kit and produces extended control of GI stromal tumors that express a mutated and constitutively activated form of c-kit. Monoclonal antibodies effectively inhibit tumor-associated antigens such as the amplified HER2 receptor in breast cancer cells (Slamon et al., 2001). Protein kinase inhibitors targeting mutant EGFR or mutant ALK in lung cancers improve disease outcomes over the use of conventional chemotherapy.

These examples emphasize that new strategies for drug discovery and development, and advances in patient care, will result from new knowledge of cancer biology. One response to the oncogene addiction paradigm has been to group cancers by shared vulnerabilities and include patients in so-called basket trials that evaluate a drug based on its target rather than particular disease entities and consider sensitivity and resistance to treatments in that context.

However, in the foreseeable future, targeted drugs and cytotoxics will continue to be used in combination. For instance, cytotoxics in combination with monoclonal antibodies such as trastuzumab or bevacizumab improve efficacy. At the same time, the toxicities of cytotoxic drugs have become more manageable with the development of better antinausea...
medications (see Chapter 50) and with granulocyte colony-stimulating factor to restore bone marrow function (see Chapters 41 and 67).

Finally, targeted drugs are helping to overcome resistance to chemotherapeutic agents by normalizing blood flow, promoting apoptosis, and inhibiting prosurvival signals from growth factor pathways. Tumor angiogenesis leads to increased interstitial pressure and diminishes delivery of drugs to tumor cells; inhibitors of angiogenesis (e.g., bevacizumab) normalize blood flow and interstitial pressure, improve drug delivery, and can thus synergize with cytotoxic drugs in the treatment of lung, colon, and other cancers. It is also thought that the combination of cytotoxic drugs or pathway inhibitors can induce tumor cell death and antigen release and thus enhance responses to immune checkpoint inhibitors or other immune modulators. This concept is part of a recommendation for the treatment of patients with melanoma (Kauffman et al., 2013) and should be relevant for a range of cancers (Sharma and Allison, 2015). The ongoing development of activating and inhibitory drugs for additional immune checkpoint pathways (Anderson et al., 2016) will provide new options for drug combinations. One challenge in immunotherapy is the highly variable responses of the immune systems of individual patients that govern the success of the treatment.

Drug Resistance

Resistance remains the major obstacle to successful cancer treatment. Resistance results from a variety of molecular changes that can defeat the best-designed treatments. Mechanisms of drug resistance include poor drug absorption and delivery; genetically determined variability in drug transport, activation, and clearance; and mutations, amplifications, or deletions in drug targets (Holohan et al., 2013). The resistance process is best understood for pathway-targeted drugs. Tumors developing resistance to bcr-abl inhibitors and to inhibitors of the EGFR typically express mutations in the target enzyme. Cells exhibiting drug-resistant mutations preexist in a patient’s tumor prior to drug treatment and are selected by drug exposure (see Figure 65–3A). Resistance to inhibitors of the EGFR may also develop through expression of an alternative receptor, c-met, which bypasses EGFR blockade and stimulates proliferation (Engelman et al., 2007). Defects in recognition of DNA breaks and overexpression of specific repair enzymes may contribute to resistance to cytotoxic drugs, and a loss of apoptotic pathways can lead to resistance to both cytotoxic and pathway-targeted drugs.

Resistance to immune checkpoint inhibitory drugs appears to follow patterns that are distinct from those of other anticancer drugs, as evidenced by their efficacy in some heavily pretreated patients. Combinations of therapies with pathway-targeted drugs as well as cytotoxic agents need to be evaluated to design effective combinations (Hughes et al., 2016). Finally, T cells carrying chimeric antigen receptors (CARs) can be directed against cancer cells that express specific antigens. CARs are engineered to contain an antigen recognition domain of a monoclonal antibody in the extracellular portion and intracellular signaling domains capable of activating T cells independently of the physiological pathway of antigen presentation by an MHC molecule (see Figures 67–3, 33–2, and 35–4). CD19-targeted CAR T cells reached a 70%–90% response rate in patients with previously treated, relapsed B-cell leukemias (Khalil et al., 2016), indicating a lack of cross-resistance with conventional therapies. This result is consistent with the requirement for effective combination therapies, that is, complementary mechanisms of action and no overlap in major toxicities.

Molecular Testing to Select Appropriate Drugs

Clinical trials and patient treatments increasingly employ results from biomarker analysis to identify patients likely to benefit from particular treatments and individuals at the greatest risk of toxicity. Some of the tests have been approved by the FDA as "companion diagnostics" in conjunction with specific drug therapies (see Table 65–1). Pretreatment testing of tumor specimens is standard practice in selecting patients for antihormonal therapy of breast cancer and for treatment with antibodies such as trastuzumab (anti-HER2). Detection of a mutated KRAS gene indicates that the tumor of a patient with colorectal cancer will not respond to anti-EGFR antibodies; in patients with lung cancers and EGFR mutations, treatment with erlotinib, gefitinib, or afatinib results in response rates of 70%, and in patients with ALK translocations, the response rates are similar for treatment with the ALK inhibitors crizotinib and ceritinib. A T790M "gatekeeper" mutation in EGFR (Kobayashi et al., 2005) accounts for about 60% of acquired resistance to first- and second-generation inhibitors but is sensitive to osimertinib, a third-generation EGFR inhibitor (Thomas et al., 2015). Overall, introduction of molecular analysis and appropriate choice of pathway-targeted inhibitors in the treatment of NSCLC has increased median survival of patients from less than 1 year to about 3 years.

*Also detectable as circulating tumor DNA (ctDNA) in blood samples.
Inherited differences in protein sequence polymorphisms or levels of RNA expression can also influence toxicity and antitumor response. For example, tandem repeats in the promoter region of the gene encoding thymidylate synthase, the target of 5-fluorouracil, determine the level of expression of the enzyme. Increased numbers of repeats are associated with increased gene expression, a lower incidence of toxicity, and a decreased rate of response in patients with colorectal cancer (Pullarkat et al., 2001). Polymorphisms of the dihydropyrimidine dehydrogenase gene, the product of which is responsible for degradation of 5-fluorouracil, are associated with decreased enzyme activity and a significant risk of overwhelming drug toxicity, particularly in the rare individual homozygous for the polymorphic genes (Van Kuilenburg et al., 2002).

Gene expression profiling, in which the levels of messenger RNA from thousands of genes are surveyed using gene arrays, has revealed tumor profiles that are highly associated with poor outcomes and warrant adjuvant chemotherapy (Sotiriou and Pusztai, 2009). As an alternative to this broad analysis, small sets of informative genes can be identified and used clinically. One example is a set of 21 genes used in the analysis of samples from patients with early stage breast cancer. Based on the known association between the expression pattern of the 21 genes and disease outcomes, the analysis of patient samples can predict the risk of disease relapse. Thus, one can identify the patients at a high risk who will benefit from adjuvant chemotherapy (Pauk et al., 2004).

Molecular Analysis and Tumor Heterogeneity

One of the caveats to conclusions drawn from the molecular analysis of tumor specimens is the dynamic evolution of cancers outlined previously (see Figure 65–3). Clinically important mutations in subclones may be missed due to geographically inadequate sampling and may provide the wrong guidance to treatment decisions. Response to treatment of different subpopulations presents a further challenge and would require multiple-site, longitudinal sampling (Shi et al., 2014).

Liquid Biopsies

More recent technology advances have made it possible to measure circulating, ctDNA in blood samples from patients with cancer (“liquid biopsies”) and to follow changes in the abundance of mutant KRAS during colon cancer treatment (Diehl et al., 2008). The analysis of ctDNA has also shown that during antiestrogen therapy of breast cancer the appearance of mutant estrogen receptor coincides with subsequent resistance to aromatase inhibitor treatment (Schiavon et al., 2015). Furthermore, mutant KRAS DNA in the circulation was increased during the treatment of patients with colon cancer with EGFR antibodies but surprisingly reverted to baseline values after cessation of the treatment. This observation demonstrates the dynamic evolution of cancer subpopulations during drug treatment (Saravega et al., 2015). The FDA recently approved a test for the presence of mutant EGFR DNA in blood samples of patients with NSCLC to select candidates for treatment with erlotinib and thus circumvent the need for a tissue biopsy. The incorporation of liquid biopsies into future treatment monitoring could provide additional molecular insights into drug efficacy and the onset of resistance.

Achieving Therapeutic Integration and Efficacy

The clinical benefit of cytotoxic drugs has primarily been measured by radiological assessment of drug effects on tumor size. Pathway-targeted agents, however, may slow or halt tumor growth, so their effects may be measured in the assessment of time to disease progression; however, for some immune checkpoint inhibitors, tumor lesions may initially increase in size due to cytotoxic lymphocyte infiltration. Thus, one of the great challenges is to assess efficacy and adjust drug regimens to achieve a therapeutic but nontoxic outcome. Treatment of patients with cancer requires a skilful interdigitation of pharmacotherapy with other modalities of treatment (e.g., surgery and irradiation). Each treatment modality carries its own risks and benefits, with the potential for both antagonistic and synergistic interactions between modalities, particularly between drugs and irradiation.

Individual patient characteristics determine the choice of modalities. Not all patients can tolerate drugs, and not all drug regimens are appropriate for a given patient. Renal and hepatic function, bone marrow reserve, general performance status, and concurrent medical problems all come into consideration in making a therapeutic plan. Other less-quantifiable considerations, such as the natural history of the tumor, the patient’s willingness to undergo difficult and potentially dangerous treatments, and the patient’s physical and emotional tolerance for adverse effects enter the equation, with the goal of balancing the likely long-term gains and risks in the individual patient. In particular, the long-term adverse effects of cytotoxic drugs have been related to the induction of cellular senescence in different organs that can adversely affect organ function and the overall well-being of patients long after completion of the treatments (Childs et al., 2015). The choice of treatment regimen should take all of this into account. Finally, in terminally ill patients, the treatment choices must be weighed carefully; the maximal length and highest quality of life may be achieved with palliative care rather than standard chemotherapy (Temel et al., 2010).

A Cautionary Note

Although advances in drug discovery and molecular profiling of tumors offer great promise for improving the outcomes of cancer treatment, a final word of caution regarding all treatment regimen deserves emphasis: The pharmacokinetics and toxicities of cancer drugs vary amongst individual patients. It is imperative to recognize toxicities early, to alter doses or discontinue offending medication to relieve symptoms and reduce risk, and to provide vigorous supportive care. Toxicities affecting the heart, lungs, nervous system, or kidneys may be irreversible if recognized late in their course, leading to permanent organ damage or death. Fortunately, such toxicities can be minimized by early recognition and by adherence to standardized protocols and to the guidelines for each drug’s use.

A Note on Treatment Regimens

Cancer treatment regimens change to reflect continuous advances in basic and clinical science: new drugs, both small molecules and biologicals; improved methods of targeting and timing of drug delivery; agents with altered pharmacokinetic properties and selectivities; the use of rational multidrug combinations; and greater knowledge of the basic cell biology of tumorigenesis, metastasis, and immune function, amongst other advances. As a consequence, this chapter and the three that follow presents relatively few detailed treatment regimens; rather, we refer the reader to the web-based resources of the U.S. FDA and the NCCN. Table 67–1 provides examples that illustrate the complexities of current therapeutic regimens for two cancers.

Acknowledgment: Paul Calabresi and Bruce A. Chabner contributed to this chapter in recent editions of this book. We have retained some of their text in the current edition.
Bibliography

I. ALKYLATING AGENTS AND PLATINUM COORDINATION COMPLEXES

**ACTIONS COMMON TO ALKYLATING DRUGS**
- Structure-Activity Relationships
- General Pharmacological Actions
- Mechanisms of Resistance to Alkylating Drugs
- Adverse Effects of Alkylating Drugs

**CLINICAL PHARMACOLOGY OF NITROGEN MUSTARDS**
- Mechlorethamine
- Cyclophosphamide
- Ifosfamide
- Melphalan
- Chlorambucil
- Bendamustine

**ETHYLENEIMINES AND METHYLMELAMINES**
- Altretamine
- Thiotepa

**ALKYL SULFONATES**
- Busulfan

**NITROSOUREAS**
- Carmustine (BCNU)
- Streptozocin

**TRIAZENES**
- Dacarbazine (DTIC)
- Temozolomide

**METHYLHYDRAZINES**
- Procarbazine

**PLATINUM COORDINATION COMPLEXES**
- Mechanisms of Action
- Resistance to Platinum Analogues
- Carboplatin
- Oxaliplatin

II. ANTIMETABOLITES

**FOLIC ACID ANALOGUES**
- Mechanism of Action
- Selective Toxicity; Rescue
- Cellular Entry and Retention
- Newer Congeners
- Mechanisms of Resistance to Antifolates

**PYRIMIDINE ANALOGUES**
- Cellular Actions of Pyrimidine Antimetabolites

**CYTIDINE ANALOGUES**
- Cytarabine (Cytosine Arabinoside; Ara-C)
- Azacitidine (5-Azacytidine); Decitabine
- Gemcitabine

**PURINE ANALOGUES**
- 6-Thiopurine Analogues
- Fludarabine Phosphate
- Cladribine
- Clofarabine (2-Chloro-2′-fluoro-arabinosyladenine)
- Nelarabine (6-Methoxy-arabinosyl-guanine)
- Pentostatin (2′-Deoxycoformycin)

III. NATURAL PRODUCTS

**MICROTUBULE-DAMAGING AGENTS**
- Vinca Alkaloids
- Eribulin
- Taxanes
- Estramustine
- Epothilones

**CAMPTOTHECIN ANALOGUES**
- Chemistry
- Mechanism of Action
- Mechanisms of Resistance
- Topotecan
- Irinotecan

**ANTIBIOTICS**
- Dactinomycin (Actinomycin D)
- Anthracyclines and Anthracenediones

**EPIPODOPHYLLOTOXINS**
- Podophyllotoxin Derivatives
- Etoposide
- Teniposide

**DRUGS OF DIVERSE MECHANISMS OF ACTION**
- Bleomycin
- Mitomycin
- Mitotane
- Trabectedin
- l-Asparaginase
- Hydroxyurea
- Retinooids
- Arsenic Trioxide

A Note on Treatment Regimens
Cancer treatment regimens change to reflect continuous advances in basic and clinical science: new drugs, both small molecules and biologicals; improved methods of targeting and timing of drug delivery; agents with altered pharmacokinetic properties and selectivities; the use of rational multidrug combinations; and greater knowledge of the basic cell biology of tumorigenesis, metastasis, and immune function, amongst other advances. As a consequence, this chapter presents relatively few detailed treatment regimens; rather, we refer the reader to the web-based resources of the U.S. FDA and the NCCN. Table 67–1 provides two examples of therapeutic regimens that illustrate the complexity of current cancer drug therapy.

I. Alkylating Agents and Platinum Coordination Complexes

HISTORY Alkylating Anticancer Drugs
The discovery and initial development of alkylating anticancer drugs are based on observations of the effects of chemical warfare in World War I (Chabner and Roberts, 2005). The pervasively toxic sulfur mustard gas that caused topical burns to skin, eyes, lungs, and mucosa also caused aplasia of the bone marrow and lymphoid tissue and ulceration of the GI tract (Krumbhaar, 1919). In 1942, Louis Goodman and Alfred Gilman, the originators of this text, demonstrated the activity of nitrogen mustards against mouse lymphoma. Their clinical studies of intravenous nitrogen mustards in patients with lymphoma launched the modern era of cancer chemotherapy (Gilman and Philips, 1946).

Actions Common to Alkylating Drugs
Six major types of alkylating agents are used in the chemotherapy of cancer: nitrogen mustards, ethyleneimines, alkyl sulfonates, nitrosoureas, triazines, and methylhydrazines. Because of similarities in their mechanisms of action and resistance, platinum complexes are also discussed with classical alkylating agents, even though they do not alkylate DNA but instead form covalent metal adducts with DNA.

The chemotherapeutic alkylating agents have in common the property of forming highly reactive carbonium ion intermediates. These reactive intermediates covalently link to sites of high electron density, such as phosphates, amines, sulfhydryls, and hydroxyl groups. Their chemotherapeutic and cytotoxic effects are directly related to the alkylation of reactive amines, oxygens, or phosphates on DNA. The N7 atom of guanine is particularly susceptible to the formation of a covalent bond with bifunctional alkylating agents and may represent the key target that determines their biological effects (Figure 66–1). Other atoms in the purine and pyrimidine bases of DNA, including N1 and N3 of the adenine ring, N3 of cytosine, and O6 of guanine, react with these agents, as do the amino and sulphydryl groups of proteins and the sulphydryl of glutathione. The general mechanisms of alkylating agents on DNA are illustrated in Figure 66–1 using mechlorethamine (nitrogen mustard).

With the bifunctional alkylating agents such as nitrogen mustard and its derivatives that are used therapeutically (Figure 66–2), the second 2-chloroethyl side chain can undergo a similar activation cross-link of two nucleic acid chains or a nucleic acid to a protein.

Figure 66–1 Mechanism of action of alkylating agents of mechlorethamine, a prototypic nitrogen mustard. A. Activation reaction. B. Alkylation of N7 of guanine. With bifunctional drugs such as nitrogen mustards (see Figure 66–2), the second 2-chloroethyl side chain can undergo a similar activation cross-link of two nucleic acid chains or the linking of a nucleic acid to a protein.

Figure 66–2 Nitrogen mustards employed in therapy.

I. Alkylating Agents and Platinum Coordination Complexes

HISTORY Alkylating Anticancer Drugs
The discovery and initial development of alkylating anticancer drugs are based on observations of the effects of chemical warfare in World War I (Chabner and Roberts, 2005). The pervasively toxic sulfur mustard gas that caused topical burns to skin, eyes, lungs, and mucosa also caused aplasia of the bone marrow and lymphoid tissue and ulceration of the GI tract (Krumbhaar, 1919). In 1942, Louis Goodman and Alfred Gilman, the originators of this text, demonstrated the activity of nitrogen mustards against mouse lymphoma. Their clinical studies of intravenous nitrogen mustards in patients with lymphoma launched the modern era of cancer chemotherapy (Gilman and Philips, 1946).

Actions Common to Alkylating Drugs
Six major types of alkylating agents are used in the chemotherapy of cancer: nitrogen mustards, ethyleneimines, alkyl sulfonates, nitrosoureas, triazines, and methylhydrazines. Because of similarities in their mechanisms of action and resistance, platinum complexes are also discussed with classical alkylating agents, even though they do not alkylate DNA but instead form covalent metal adducts with DNA.

The chemotherapeutic alkylating agents have in common the property of forming highly reactive carbonium ion intermediates. These reactive intermediates covalently link to sites of high electron density, such as phosphates, amines, sulfhydryls, and hydroxyl groups. Their chemotherapeutic and cytotoxic effects are directly related to the alkylation of reactive amines, oxygens, or phosphates on DNA. The N7 atom of guanine is particularly susceptible to the formation of a covalent bond with bifunctional alkylating agents and may represent the key target that determines their biological effects (Figure 66–1). Other atoms in the purine and pyrimidine bases of DNA, including N1 and N3 of the adenine ring, N3 of cytosine, and O6 of guanine, react with these agents, as do the amino and sulphydryl groups of proteins and the sulphydryl of glutathione. The general mechanisms of alkylating agents on DNA are illustrated in Figure 66–1 using mechlorethamine (nitrogen mustard).

With the bifunctional alkylating agents such as nitrogen mustard and its derivatives that are used therapeutically (Figure 66–2), the second 2-chloroethyl side chain can undergo a similar activation cross-link of two nucleic acid chains or the linking of a nucleic acid to a protein.

Figure 66–1 Mechanism of action of alkylating agents of mechlorethamine, a prototypic nitrogen mustard. A. Activation reaction. B. Alkylation of N7 of guanine. With bifunctional drugs such as nitrogen mustards (see Figure 66–2), the second 2-chloroethyl side chain can undergo a similar activation cross-link of two nucleic acid chains or the linking of a nucleic acid to a protein.

Figure 66–2 Nitrogen mustards employed in therapy.
The ultimate cause of cell death related to DNA damage is not known. Specific cellular responses include cell-cycle arrest and attempts to repair DNA. The specific repair enzyme complex utilized will depend on two factors: the chemistry of the adduct formed and the repair capacity of the cell involved. The process of recognizing and repairing DNA generally requires an intact NER complex but may differ with each drug and with each tumor. Alternatively, recognition of extensively damaged DNA by p53 can trigger apoptosis. However, faulty DNA damage repair mechanisms and mutations of p53 can lead to resistance to alkylating drugs (Kastan, 1999).

**Structure-Activity Relationships**

Although alkylating agents share the capacity to alkylate biologically important molecules, modification of the basic backbone structure changes reactivity, lipophilicity, active transport across biological membranes, sites of macromolecular attack, and mechanisms of DNA repair, all of which determine drug activity in vivo. For several of the most valuable agents (e.g., cyclophosphamide, ifosfamide), the active alkylating moieties are generated in vivo through hepatic metabolism (Figure 66–3).

The newest (2008) approved alkylating agent, bendamustine, has the typical chloroethyl reactive groups in nitrogen mustard (M) attached to a benzimidazole backbone. The unique properties and activity of this drug may derive from this purine-like structure; the agent produces slowly repaired DNA cross-links, lacks cross-resistance with other classical alkylators (Leoni et al., 2008), and is approved for treatment of CLL and large-cell lymphomas refractory to standard alkylators.

**Figure 66–3** Activation and metabolism of cyclophosphamide. Cyclophosphamide is activated (hydroxylated) by CYP2B, with subsequent transport of the activated intermediate to sites of action. The selectivity of cyclophosphamide against certain malignant tissues may result in part from the capacity of normal tissues to degrade the activated intermediates via aldehyde dehydrogenase, glutathione transferase, and other pathways. Ifosfamide is structurally similar to cyclophosphamide (see Figure 66–2); whereas cyclophosphamide has two chloroethyl groups on the exocyclic nitrogen atom, one of the 2-chloroethyl groups of ifosfamide is on the cyclic phosphoramidate nitrogen of the oxazaphosphorine ring. Ifosfamide is activated by hepatic CYP3A4 and proceeds more slowly than activation of cyclophosphamide, with greater production of dechlorinated metabolites and chloroacetaldehyde. These differences in metabolism likely account for the higher doses of ifosfamide required for equitoxic effects, the greater neurotoxicity of ifosfamide, and perhaps differences in the antitumor spectra of cyclophosphamide and ifosfamide.

**General Pharmacological Actions**

**Cytotoxic Actions**

The capacity of alkylating agents to interfere with DNA integrity and function and to induce cell death in rapidly proliferating tissues provides the basis for their therapeutic and toxic properties. Acute effects manifest primarily against rapidly proliferating tissues; however, certain alkylating agents may have damaging effects on tissues with normally low mitotic indices (e.g., liver, kidney, and mature lymphocytes); effects in these tissues usually are delayed. Lethality of DNA alkylaion depends on the recognition of the adduct, the creation of DNA strand breaks by repair enzymes, and an intact apoptotic response. In nondividing cells, DNA damage activates a checkpoint that depends on the presence of a normal p53 gene. Cells thus blocked in the G1/S interface either repair DNA alkylation or undergo apoptosis. Malignant cells with mutant or absent p53 fail to suspend cell-cycle progression, do not undergo apoptosis, and can exhibit resistance to these drugs.
enzyme, when expressed in human gliomas, produces resistance to nitro-soureas and to other methylating agents, including dacarbazine, temozolomide, and procarbazine.

**Distinction Between Mono- and Bi-functional Agents**

Although DNA is the ultimate target of all alkylating agents, there is a crucial distinction between the bifunctional agents, in which cytotoxic effects predominate, and the monofunctional methylating agents (procarbazine, temozolomide), which have greater capacity for mutagenesis and carcinogenesis. This suggests that the cross-linking of DNA strands represents a much greater threat to cellular survival than do other effects, such as single-base alkylation and the resulting depurination and single-chain scission. Conversely, simple methylation may be bypassed by DNA polymerases, leading to mispairing reactions that permanently modify a DNA sequence. These new sequences are transmitted to subsequent generations and may result in mutagenesis or carcinogenesis. Some methylating agents, such as procarbazine, are highly carcinogenic.

Adduct recognition systems and DNA repair systems play important roles in removing adducts and thereby determine the selectivity of action against particular cell types and the acquisition of resistance to alkylating agents. Alkylation of a single strand of DNA (monoadducts) is repaired by the NER pathway. The less frequent cross-links require participation of multiple proteins. Their absence or mutation, as in Fanconi anemia, leads to extreme sensitivity to DNA cross-linking, creating mispairing of thymine residues, and triggering apoptosis. The Fanconi pathway, consisting of 12 proteins, recognizes adducts and signals the need for repair of a broad array of DNA-damaging drugs and irradiation. Absence or inactivation of components of this pathway leads to increased sensitivity to DNA damage. Conversely, for the methylating drugs, nitrosoureas, cisplatin and carboplatin, and thiopurine analogues, the MMR pathway is essential for cytotoxicity, causing strand breaks at sites of adduct formation, creating mispairing of thymine residues, and triggering apoptosis.

**Mechanisms of Resistance to Alkylating Drugs**

Resistance to an alkylating agent develops rapidly when it is used as a single agent. Specific biochemical changes implicated in the development of resistance include the following:

- decreased permeation of actively transported drugs (e.g., melphalan, chlorambucil, cyclophosphamide, and ifosfamide) cause myelosuppression, with a nadir of the peripheral blood granulocyte count at 6–10 days and recovery in 14–21 days. Cyclophosphamide has lesser effects on peripheral blood platelet counts than do the other agents. Busulfan suppresses all blood elements, particularly stem cells, and may produce a prolonged and cumulative myelosuppression lasting months or even years. For this reason, it is used as a preparative regimen in allogeneic bone marrow transplantation.

**Marrow**

Most alkylating agents cause dose-limiting toxicity to marrow cells and, to a lesser extent, intestinal mucosa. Most alkylating agents (i.e., melphalan, chlorambucil, cyclophosphamide, and ifosfamide) cause myelosuppression, with a nadir of the peripheral blood granulocyte count at 6–10 days and recovery in 14–21 days. Cyclophosphamide has lesser effects on peripheral blood platelet counts than do the other agents. Busulfan suppresses all blood elements, particularly stem cells, and may produce a prolonged and cumulative myelosuppression lasting months or even years. For this reason, it is used as a preparative regimen in allogeneic bone marrow transplantation. Carmustine and other chloroethyl-nitrosoureas cause delayed and prolonged suppression of both platelets and granulocytes, reaching a nadir 4–6 weeks after drug administration and reversing slowly thereafter. Both cellular and humoral immunity are suppressed by alkylating agents, which have, therefore, been used to treat various autoimmune diseases. Immunosuppression is reversible at usual doses, but opportunistic infections may occur with extended treatment.

**Mucosa, Hair Follicles**

Alkylating agents are highly toxic to dividing mucosal cells and to hair follicles, leading to oral mucosal ulceration, intestinal denudation, and alopecia. Mucosal effects are particularly damaging in high-dose chemotherapy protocols associated with bone marrow transplantation, as they predispose to bacterial sepsis arising from the GI tract. In these protocols,
LYmphocytic leukemia, induced by treatment, is often associated with an increased risk of phenytoin, an antiseizure medication. The more unstable alkylating agents (e.g., mechlorethamine and the nitrosoureas) have strong vesicant properties, damage veins with repeated use, and, if extravasated, produce ulceration. All alkylating agents have shown significant interpatient variability and increases with successive doses in high-dose regimens but appears to be saturable at concentrations of the parent compound greater than 150 μM. 4-Hydroxycyclophosphamide may be oxidized further by aldehyde oxidase, either in liver or in tumor tissue, to inactive metabolites. 4-Hydroxycyclophosphamide and its tautomer, aldosphamide, travel in the circulation to tumor cells, where aldosphamide cleaves spontaneously, generating stoichiometric amounts of phosphoramidate mustard and acrolein. Phosphoramidate must be responsible for antitumor effects, while acrolein causes hemorrhagic cystitis often seen during therapy with cyclophosphamide.

**Mechlorethamine**

Mechlorethamine HCl was the first clinically used nitrogen mustard and is the most reactive of the drugs in this class. It is used topically for treatment of CTCL as a solution that is rapidly mixed and applied to affected areas. It has been largely replaced by cyclophosphamide, melphalan, and other more stable alkylating agents.

**Cyclophosphamide**

**ADME**

Cyclophosphamide is well-absorbed orally and is activated to the 4-hydroxy intermediate (see Figure 66–3). Its rate of metabolic activation exhibits significant interpatient variability and increases with successive doses in high-dose regimens but appears to be saturable at concentrations of the parent compound greater than 150 μM. 4-Hydroxycyclophosphamide may be oxidized further by aldehyde oxidase, either in liver or in tumor tissue, to inactive metabolites. 4-Hydroxycyclophosphamide and its tautomer, aldosphamide, travel in the circulation to tumor cells, where aldosphamide cleaves spontaneously, generating stoichiometric amounts of phosphoramidate mustard and acrolein. Phosphoramidate mustard is responsible for antitumor effects, while acrolein causes hemorrhagic cystitis often seen during therapy with cyclophosphamide.

**Clinical Pharmacology of Nitrogen Mustards**

**Mechlorethamine**

Mechlorethamine HCl was the first clinically used nitrogen mustard and is the most reactive of the drugs in this class. It is used topically for treatment of CTCL as a solution that is rapidly mixed and applied to affected areas. It has been largely replaced by cyclophosphamide, melphalan, and other more stable alkylating agents.

**Cyclophosphamide**

**ADME**

Cyclophosphamide is well-absorbed orally and is activated to the 4-hydroxy intermediate (see Figure 66–3). Its rate of metabolic activation exhibits significant interpatient variability and increases with successive doses in high-dose regimens but appears to be saturable at concentrations of the parent compound greater than 150 μM. 4-Hydroxycyclophosphamide may be oxidized further by aldehyde oxidase, either in liver or in tumor tissue, to inactive metabolites. 4-Hydroxycyclophosphamide and its tautomer, aldosphamide, travel in the circulation to tumor cells, where aldosphamide cleaves spontaneously, generating stoichiometric amounts of phosphoramidate mustard and acrolein. Phosphoramidate mustard is responsible for antitumor effects, while acrolein causes hemorrhagic cystitis often seen during therapy with cyclophosphamide.
cyclophosphamide. Patients should receive vigorous intravenous hydration during high-dose treatment. Brisk hematuria in a patient receiving daily oral therapy should lead to immediate drug discontinuation. Refractory bladder hemorrhage can become life-threatening and may require cystectomy for control of bleeding. Inappropriate secretion of antidiuretic hormone has been observed (usually at doses greater than 50 mg/kg) and can lead to water intoxication because these patients usually are vigorously hydrated. In addition to the cystitis (counteracted by MESNA and diuresis), GI, pulmonary, renal, hepatic, and cardiac toxicities (hemorrhagic myocardial necrosis) may occur after high-dose therapy with total doses greater than 200 mg/kg.

**Ifosfamide**

Ifosfamide is an analogue of cyclophosphamide. Severe urinary tract and CNS toxicity initially limited the use of ifosfamide, but adequate hydration and coadministration of MESNA have reduced its bladder toxicity. CNS toxicity is handled with methylene blue.

**ADME**

Ifosfamide has a plasma elimination $t_{1/2}$ of about 1.5 h after doses of 3.8–5 g/m² and a somewhat shorter $t_{1/2}$ at lower doses; its pharmacokinetics are highly variable due to variable rates of hepatic metabolism (see legend to Figure 66–3).

**Therapeutic Uses**

Ifosfamide is approved for treatment of patients with relapsed germ cell testicular cancer and is frequently used for first-time treatment of pediatric or adult patients with sarcomas. It is a common component of high-dose chemotherapy regimens with bone marrow or stem cell rescue. In nonmyeloablative regimens, ifosfamide is infused intravenously over at least 30 min at a dose of 1.2 g/m²/d or less for 5 days. Intravenous MESNA is given as bolus injections in a dose equal to 20% of the ifosfamide dose concomitantly and an additional 20% again 4 and 8 h later, for a total MESNA dose of 60% of the ifosfamide dose. Alternatively, MESNA may be given concomitantly in a single dose equal to the ifosfamide dose. Patients also should receive at least 2 L of oral or intravenous fluid daily. Treatment cycles are repeated every 3–4 weeks.

**Adverse Effects**

Ifosfamide has a similar toxicity profile as cyclophosphamide, although it causes greater platelet suppression, neurotoxicity, nephrotoxicity, and urothelial damage. In high-dose regimens (i.e., total doses of 12–14 g/m²), it may cause severe neurological toxicity, including hallucinations, coma, and death, with symptoms appearing 12 h to 7 days after beginning the ifosfamide infusion. This toxicity may result from a metabolite, chloroacetaldehyde. Ifosfamide also causes nausea, vomiting, anorexia, leukopenia, nephrotoxicity, and VOD of the liver.

**Melphalan**

The alkylating agent melphalan primarily is used to treat multiple myeloma and, less commonly, in high-dose chemotherapy with marrow transplantation. The general pharmacological and cytotoxic actions of melphalan are similar to those of other bifunctional alkylators. The drug is not a vesicant.

**ADME**

Oral melphalan is absorbed in an inconsistent manner and, for most indications, is given as an intravenous infusion. The drug has a plasma $t_{1/2}$ of about 45–90 min; 10%–15% of an administered dose is excreted unchanged in the urine. Patients with decreased renal function may develop unexpectedly severe myelosuppression.

**Therapeutic Uses and Adverse Effects**

Melphalan for multiple myeloma is administered orally for 4–7 days every 28 days, with dexamethasone or thalidomide. Treatment is repeated at 4-week intervals based on response and tolerance. Dosage adjustments should be based on blood cell counts. Melphalan also may be used in myeloablative regimens followed by bone marrow or peripheral blood stem cell reconstitution. The toxicity of melphalan is mostly hematological and is similar to that of other alkylating agents. Nausea and vomiting are less frequent. The drug causes less alopecia and, rarely, renal or hepatic dysfunction.

**Chlorambucil**

The cytoxic effects of chlorambucil on the bone marrow, lymphoid organs, and epithelial tissues are similar to those observed with other nitrogen mustards. As an orally administered agent, chlorambucil is well tolerated in small daily doses and provides flexible titration of blood counts. Nausea and vomiting may result from single oral doses of 20 mg or greater.

**ADME**

Oral absorption of chlorambucil is adequate and reliable. The drug has a $t_{1/2}$ in plasma of about 1.5 h and is hydrolyzed to inactive products.

**Therapeutic Uses and Adverse Effects**

Chlorambucil is almost exclusively used in treating CLL. In treating CLL, chlorambucil is given once daily and continued for 3–6 weeks. With a fall in the peripheral total leukocyte count or clinical improvement, the dosage is titrated to maintain neutrophils and platelets at acceptable levels. Maintenance therapy often is required to maintain clinical response. Chlorambucil treatment may continue for months or years, achieving its effects gradually and often without significant toxicity to a compromised bone marrow. Marked hypoplasia of the bone marrow may be induced with excessive doses, but the myelosuppressive effects are moderate, gradual, and rapidly reversible. GI discomfort, azoospermia, amenorrhea, pulmonary fibrosis, seizures, dermatitis, and hepatotoxicity rarely may be encountered. A marked increase in the incidence of AML and other tumors has been noted in the treatment of polycythemia vera and in patients with breast cancer receiving chlorambucil as adjuvant chemotherapy.

**Bendamustine**

Bendamustine is approved for treatment of CLL and non-Hodgkin lymphoma. Bendamustine is given as a 30-min intravenous infusion on days 1 and 2 of a 28-day cycle. Lower doses may be indicated in heavily pre-treated patients. Bendamustine is rapidly degraded through sulphydryl interaction and adduct formation with macromolecules; less than 5% of the parent drug is excreted in the urine intact. N-Demethylation and oxidation produce metabolites that have antitumor activity, but less than that of the parent molecule. The parent drug has a plasma $t_{1/2}$ of about 30 min. The clinical toxicity pattern of bendamustine is typical of alkylators, with a rapidly reversible myelosuppression and mucositis, both generally tolerable.

**Ethyleneimines and Methylmelamines**

Although nitrogen mustards containing chloroethyl groups constitute the most widely used class of alkylating agents, other alkylators such as ethyleneimines with greater chemical stability and well-defined activity in specific types of cancer have value in clinical practice.

**Altretamine**

Altretamine is structurally similar to triethylenemelamine (TEM). Its precise mechanism of cytotoxicity is unknown, although it can alkylate DNA and proteins. It is a palliative treatment of patients with persistent or recurrent ovarian cancer following cisplatin-based combination therapy. The usual dosage of altretamine as a single agent in ovarian cancer is 260 mg/m²/d in four divided doses, for 14 or 21 consecutive days out of a 28-day cycle, for up to 12 cycles.

**ADME**

Altretamine is well absorbed from the GI tract; its elimination $t_{1/2}$ is 4–10 h. The drug undergoes rapid demethylation in the liver; the principal metabolites are pentamethylmelamine and tetramethyl melamine.
Adverse Effects
The main toxicities of altretamine are myelosuppression and neurotoxicity. Altretamine causes both peripheral and central neurotoxicity (ataxia, depression, confusion, drowsiness, hallucinations, dizziness, and vertigo). Neurological symptoms abate on discontinuation of therapy. Peripherally blood counts and a neurological examination should be performed prior to the initiation of each course of therapy. Therapy should be interrupted for at least 14 days and subsequently restarted at a lower dosage if the white cell count falls to less than 2000 cells/mm$^3$ or the platelet count falls to less than 75,000 cells/mm$^3$ or if neurotoxic or intolerable GI symptoms occur. If neurological symptoms fail to stabilize on the reduced-dose schedule, altretamine should be discontinued. Nausea and vomiting also are common side effects and may be dose limiting. Renal dysfunction may necessitate discontinuing the drug. Other rare adverse effects include rashes, alopecia, and hepatic toxicity. Severe, life-threatening orthostatic hypotension may develop in patients who receive MAO inhibitors, amitriptyline, imipramine, or phenelzine concurrently with altretamine.

Thiotepa
Thiotepa consists of three ethyleneimine groups stabilized by attachment to the nuclophilic thioephosphoryl base. Its current use is primarily for high-dose chemotherapy regimens. Hepatic CYPs rapidly convert thiotepa to its desulfurated primary metabolite, TEPA. Both thiotepa and TEPA form DNA cross-links.

**ADME**
Within hours of thiotepa administration, TEPA becomes the predominant form of the drug present in plasma. The parent compound has a plasma $t_{1/2}$ of 1.2–2 h; TEPA has a longer $t_{1/2}$ of 3–24 h. Thiotepa pharmacokinetics essentially are the same in children as in adults at conventional doses ($\leq 80$ mg/m$^2$), and drug and metabolite $t_{1/2}$ are unchanged in children receiving high-dose therapy of 300 mg/m$^2$ for 3 days. Less than 10% of the administered drug appears in urine as the parent drug or the primary metabolite.

Adverse Effects
Toxicities include myelosuppression and, to a lesser extent, mucositis. Myelosuppression tends to develop somewhat later than with cyclophosphamide, with leukopenic nadirs at 2 weeks and platelet nadirs at 3 weeks. In high doses, thiotepa may cause neurotoxic symptoms, including coma and seizures.

**Alkyl Sulfonates**

Busulfan
Busulfan exerts few pharmacological actions other than myelosuppression at conventional doses and, prior to the advent of imatinib mesylate, was a standard agent for patients in the chronic phase of myelocytic leukemia and caused a severe and prolonged pancytopenia in some patients. Busulfan now is primarily used in high-dose regimens, in which pulmonary fibrosis, GI mucosal damage, and hepatic VOD are important toxicities.

**ADME**
Busulfan is well absorbed after oral administration and has a plasma $t_{1/2}$ of 2–3 h. The drug is conjugated to GSH by GSTA1A and further metabolized by CYP-dependent pathways; its major urinary metabolite is methanesulfonic acid. In high doses, children less than 18 years of age clear the drug two to four times faster than adults and tolerate higher doses. Busulfan clearance varies considerably amongst patients. VOD is associated with high AUC ($>1500$ μM × min) and slow clearance, leading to recommendations for dose adjustment based on drug-level monitoring.

A target steady-state concentration of 600–900 ng/mL in plasma in adults or AUC < 1000 μM × min in children achieves an appropriate balance between toxicity and therapeutic benefit.

Therapeutic Uses
In treating CML, the initial oral dose of busulfan varies with the total leukocyte count and the severity of the disease; daily doses are adjusted to subsequent hematological and clinical responses, with the aim of reducing the total leukocyte count to 10,000 cells/mm$^3$ or less. A decrease in the leukocyte count usually is not seen during the first 10–15 days of treatment, and the leukocyte count may actually increase during this period. Because the leukocyte count may fall for more than 1 month after discontinuing the drug, it is recommended that busulfan be withdrawn when the total leukocyte count has declined to about 15,000 cells/mm$^3$. A normal leukocyte count usually is achieved within 12–20 weeks. During remission, daily treatment resumes when the total leukocyte count reaches about 50,000 cells/mm$^3$.

In high-dose therapy, anticonvulsants must be used concomitantly to protect against acute CNS toxicities, including tonic-clonic seizures that may occur several hours after each dose. Although phenytoin is a frequent choice, phenytoin induces the GSTs that metabolize busulfan, reducing its AUC by about 20%. In patients requiring concomitant antiseizure medication, non–enzyme-inducing benzodiazepines such as lorazepam and clonazepam are recommended as an alternative to phenytoin. If phenytoin is used concurrently, plasma busulfan levels should be monitored and the busulfan dose adjusted accordingly.

Adverse Effects
The toxic effects of busulfan are related to its myelosuppressive properties; prolonged thrombocytopenia may occur. Occasionally, patients experience nausea, vomiting, and diarrhea. Long-term use leads to impotence, sterility, amenorrhea, and fetal malformation. Rarely, patients develop asthenia and hypotension. High-dose busulfan causes VOD of the liver in 10% or fewer of patients, as well as seizures, hemorrhagic cystitis, permanent alopecia, and cataracts. The coincidence of VOD and hepatotoxicity is increased by its coadministration with drugs that inhibit CYPs, including imidazoles and metronidazole, possibly through inhibition of the clearance of busulfan or its toxic metabolites.

Nitrosoureas
The nitrosoureas have an important role in the treatment of brain tumors and find occasional use in treating lymphomas and in high-dose regimens with bone marrow reconstitution. They function as bifunctional alkylating agents but differ from conventional nitrogen mustards in both pharmacological and toxicological properties.

Carmustine (BCNU) and lomustine (CCNU, not discussed in detail) are highly lipophilic and thus readily cross the blood-brain barrier, an important property in the treatment of brain tumors. Unfortunately, with the exception of streptozocin, nitrosoureas cause profound and delayed myelosuppression, with recovery 4–6 weeks after a single dose. Long-term treatment with the nitrosoureas, especially semustine (methyl-CCNU), has resulted in renal failure. As with other alkylating agents, the nitrosoureas are highly carcinogenic and mutagenic. They generate both alkylating and carbamylating moieties (see Figure 66–4).

Carmustine (BCNU)
Carmustine’s major action is its alkylation of DNA at the O6-guanine position, an adduct repaired by MGMT. Methylation of the MGMT promoter inhibits its expression in about 30% of primary gliomas and is associated with sensitivity to nitrosoureas. In high doses with bone marrow rescue, carmustine produces hepatic VOD, pulmonary fibrosis, renal failure, and secondary leukemia.

**ADME**
Carmustine is unstable in aqueous solution and in body fluids. After intravenous infusion, it disappears from the plasma with a highly variable $t_{1/2}$ of 15–90 min or more. Approximately 30%–80% of the drug appears in the urine within 24 h as degradation products. The alkylating metabolites
enter rapidly into the CSF, and their concentrations in the CSF reach 15%–30% of the concurrent plasma values.

**Therapeutic Uses**

Carmustine (BCNU) is administered intravenously over 1–2 h and repeated every 6 weeks. Because of its ability to cross the blood-brain barrier, carmustine has been used in the treatment of malignant gliomas. An implantable carmustine wafer is available for use as an adjunct to surgery for recurrent glioblastoma multiforme.

**Streptozocin**

Streptozocin (or streptozotocin) has a methyluracil moiety attached to the 2-carbon of glucose. It has a high affinity for cells of the islets of Langerhans and causes diabetes in experimental animals.

**ADME**

Streptozocin is rapidly degraded following intravenous administration. The $t_{1/2}$ of the drug is about 15 min. Only 10%–20% of a dose is recovered intact in the urine.

**Therapeutic Uses**

Streptozocin is used in the treatment of human pancreatic islet cell carcinoma and carcinoid tumors. It is administered intravenously once daily for 5 days; this course is repeated every 6 weeks. Alternatively, a higher dose can be given weekly for 2 weeks, and the weekly dose then can be increased as tolerated.

**Adverse Effects**

Nausea is frequent. Mild, reversible renal or hepatic toxicity occurs in approximately two-thirds of cases; in fewer than 10% of patients, renal toxicity may be cumulative with each dose and may lead to irreversible renal failure. Streptozocin should not be given with other nephrotoxic drugs. Hematological toxicities (anemia, leukopenia, thrombocytopenia) occur in 20% of patients.

**Triazenes**

**Dacarbazine (DTIC)**

Dacarbazine functions as a methylating agent after metabolic activation to the monomethyl triazeno metabolite MTIC. It kills cells in all phases of the cell cycle. Resistance has been ascribed to the removal of methyl groups from the O6-guanine bases in DNA by MGMT.

**ADME**

Dacarbazine is administered intravenously. After an initial rapid phase ($t_{1/2}$ of about 20 min), dacarbazine is cleared from plasma with a terminal $t_{1/2}$ of about 5 h. The $t_{1/2}$ is prolonged in the presence of hepatic or renal disease. Almost 50% of the compound is excreted intact in the urine by tubular secretion.

**Therapeutic Uses**

The primary clinical indication for dacarbazine is in the chemotherapy of Hodgkin disease. In combination with other drugs for Hodgkin disease, dacarbazine is given on day 1 and 15 and repeated every 4 weeks for up to 6 cycles (see NCCN). It is modestly effective against malignant melanoma and adult sarcomas. Dacarbazine for malignant melanoma is given for 5 days and repeated every 3 weeks. Extravasation of the drug may cause tissue damage and severe pain. Its use in patients with melanoma has largely been replaced by immune checkpoint inhibitors and agents targeting the typically activated mitogen-activated protein kinase pathway (see Chapter 67).

**Adverse Effects**

Dacarbazine induces nausea and vomiting in more than 90% of patients; vomiting usually develops 1–3 h after treatment and may last up to 12 h. Myelosuppression, with both leukopenia and thrombocytopenia, is mild and readily reversible within 1–2 weeks. A flu-like syndrome may occur. Hepatotoxicity, alopecia, facial flushing, neurotoxicity, and dermatological reactions are less common adverse effects.

**Temozolomide**

Temozolomide is the standard agent, in combination with radiation therapy, for patients with malignant glioma and astrocytoma. Temozolomide, like dacarbazine, forms the methylating metabolite MTIC and kills cells in all phases of the cell cycle. It is more active in MGMT deficient tumors.

**ADME**

Temozolomide is administered orally and has a bioavailability approaching 100%. Plasma levels of the parent drug decline with a $t_{1/2}$ of 1–2 h. The primary active metabolite MTIC reaches a maximum plasma concentration (150 ng/mL) 90 min after a dose and declines with a $t_{1/2}$ of 2 h. Little intact drug is recovered in the urine, the primary urinary metabolite being the inactive imidazole carboxamidine.

**Adverse Effects**

The toxicities of temozolomide mirror those of DTIC. Hematological monitoring is necessary to guide dosing adjustments.

**Methylhydrazines**

**Procarbazine**

Procarbazine is used in malignant brain tumors and in combination regimens for patients with Hodgkin disease.

**Mechanisms of Action**

The antineoplastic activity of procarbazine results from its conversion by CYP-mediated hepatic oxidative metabolism to highly reactive alkylating species that methylate DNA. Activated procarbazine can produce chromosomal damage, including chromatid breaks and translocations, consistent with its mutagenic and carcinogenic actions. Resistance to procarbazine develops rapidly when it is used as a single agent; one mechanism of resistance results from increased expression of MGMT, which repairs methylation of guanine.

**ADME**

The pharmacokinetic behavior of procarbazine has not been thoroughly defined. The drug is extensively metabolized by CYPs to azo, methylafoxoy, and benzylazoxy intermediates, which are found in the plasma and yield the alkylating metabolites in tumor cells. In patients with brain cancer, the concurrent use of antiseizure drugs that induce hepatic CYPs does not significantly alter the pharmacokinetics of the parent drug.

**Therapeutic Uses**

Procarbazine is used in combination regimens such as MOPP for Hodgkin disease. It is also used in treating gliomas as part of the PVC (procarbazine, vincristine and CCNU) regimen.

**Adverse Effects**

The most common toxic effects include leukopenia and thrombocytopenia, which begin during the second week of therapy and reverse within 2 weeks off treatment. GI symptoms such as mild nausea and vomiting occur in most patients; diarrhea and rash are noted in 5%–10% of cases. Behavioral disturbances also have been reported. Because procarbazine augments sedative effects, the concomitant use of CNS depressants should be avoided. The drug is a weak MAO inhibitor; it blocks the metabolism of catecholamines, sympathometamics, and dietary tyramine and thus may provoke hypertension in patients concurrently exposed to these. Procarbazine has disulfiram-like actions; therefore, the ingestion of alcohol should be avoided. The drug is highly carcinogenic, mutagenic, and teratogenic and is associated with a 5%–10% risk of acute leukemia in patients treated with MOPP. The highest risk is for patients who also receive radiation therapy. Procarbazine is a potent immunosuppressive agent. It causes infertility, particularly in males.
Platinum Coordination Complexes

Platinum coordination complexes have broad antineoplastic activity and have become the foundation for treatment of ovarian, head and neck, bladder, esophagus, lung, and colon cancers. Although cisplatin and other platinum complexes do not form carbonium ion intermediates like other alkylating agents or formally alkylate DNA, they covalently bind to nucleophilic sites on DNA and share many pharmacological attributes with alkylators.

Mechanisms of Action

Cisplatin, carboplatin, and oxaliplatin enter cells by the high-affinity Cu⁺ transporter CTR1 (SLC31A1, a member of the solute carrier family; see Chapter 5) and in doing so contribute to the degradation of the transporter. The compounds are actively extruded from cells by ATP7A and ATP7B copper exporters and by MRPs; variable expression of these transporters may contribute to clinical resistance, along with a variety of other epigenetic phenomena (Shen et al., 2012). Inside the cell, the chloride, cyclohexane, or oxalate ligands of the analogues are displaced by water molecules, yielding a positively charged molecule that reacts with nucleophilic sites on DNA and proteins.

Aquation of cisplatin is favored at the low concentrations of Cl⁻ inside the cell and in the urine. High concentrations of Cl⁻ stabilize the drug, explaining the effectiveness of Cl⁻ diuresis in preventing nephrotoxicity. The activated platinum complexes can react with electron-rich regions, such as sulphydryls, and with various sites on DNA, forming both intrastrand and interstrand cross-links. The DNA-platinum adducts inhibit replication and transcription, lead to single- and double-stranded breaks and miscoding, and if recognized by p53 and other checkpoint proteins, cause induction of apoptosis. Adduct formation is an important predictor of clinical response (Reed et al., 1998). The analogues differ in the conformation of their adducts and the effects of adduct on DNA structure and function. Oxaliplatin and carboplatin are slower to form adducts. The oxaliplatin adducts are bulkier and less readily repaired, create a different pattern of distortion of the DNA helix, and differ from cisplatin adducts in the pattern of hydrogen bonding to adjacent segments of DNA (Sharma et al., 2007).

Unlike the other platinum analogues, oxaliplatin exhibits a cytotoxicity that does not depend on an active MMR system, which may explain its greater activity in colorectal cancer. It also seems less dependent on the presence of HMG proteins that are required by the other platinum derivatives. Testicular cancers have a high concentration of HMG proteins and are quite sensitive to cisplatin. Basal-type breast cancers, such as those with BRCA1 and BRCA2 mutations, lack HER2 amplification and hormone-receptor expression and appear to be uniquely susceptible to cisplatin through their upregulation of apoptotic pathways governed by p53 and p73 (Deyoung and Ellisen, 2007). The cell cycle specificity of cisplatin differs amongst cell types; the effects of cross-linking are most pronounced during the S phase. The platinum analogues are mutagenic, teratogenic, and carcinogenic. Cisplatin- or carboplatin-based chemotherapy for ovarian cancer is associated with a 4-fold increased risk of developing secondary leukemia.

Resistance to Platinum Analogues

Resistance to the platinum analogues likely is multifactorial; the compounds differ in their degree of cross-resistance. Carboplatin shares cross-resistance with cisplatin in most experimental tumors, while oxaliplatin does not.

A number of factors influence sensitivity to platinum analogues in experimental cells, including intracellular drug accumulation and intracellular levels of glutathione and other sulphydryls, such as metallothionein, that bind to and inactivate the drug and rates of repair of DNA adducts. Repair of platinum-DNA adducts requires participation of the NER pathway. Inhibition or loss of NER increases sensitivity to cisplatin in patients with ovarian cancer, while overexpression of NER components is associated with poor response to cisplatin- or oxaliplatin-based therapy in lung, colon, and gastric cancer (Paré et al., 2008). Resistance to cisplatin, but not oxaliplatin, appears to be partly mediated through loss of function in the MMR proteins. In the absence of effective repair of DNA-platinum adducts, sensitive cells cannot replicate or transcribe affected portions of the DNA strand. Some DNA polymerases can bypass adducts, possibly contributing to resistance. Overexpression of copper efflux transporters ATP7A and ATP7B correlates with poor survival after cisplatin-based therapy for ovarian cancer (Shen et al., 2012).

Cisplatin

ADME

Cisplatin is given only intravenously. To prevent renal toxicity, it is important to establish a chloride diuresis by the infusion of 1–2 L of normal saline prior to treatment. The appropriate amount of cisplatin is then diluted in a solution containing dextrose, saline, and mannitol and administered intravenously over 4–6 h. Because aluminum inactivates cisplatin, the drug should not come in contact with needles or other infusion equipment that contain aluminum during its preparation or administration. After intravenous administration, cisplatin has an initial plasma elimination t½ of 25–50 min; concentrations of total (bound and unbound) drug fall thereafter, with a t½ of 24 h or more. More than 90% of the platinum in the blood is covalently bound to plasma proteins. High concentrations of cisplatin are found in the kidney, liver, intestine, and testes; cisplatin penetrates poorly into the CNS. Only a small portion of the drug is excreted by the kidney during the first 6 h; by 24 h, up to 25% is excreted, and by 5 days, up to 43% of the administered dose is recovered in the urine, mostly covalently bound to protein and peptides. Biliary or intestinal excretion of cisplatin is minimal.

Therapeutic Uses

Cisplatin, in combination with bleomycin, etoposide, or with ifosfamide and vinblastine, cures 90% of patients with testicular cancer. Used with paclitaxel, cisplatin or carboplatin induces complete response in the majority of patients with carcinoma of the ovary. Cisplatin produces responses in cancers of the bladder, head and neck, cervix, and endometrium; all forms of carcinoma of the lung; anal and rectal carcinomas; and neoplasms of childhood. The drug also sensitizes cells to radiation therapy and enhances control of locally advanced lung, esophageal, and head and neck tumors when given with irradiation.

Adverse Effects

Cisplatin-induced nephrotoxicity has been largely ameliorated by forced pretreatment hydration and chloride diuresis. Amifostine, a thiophosphate cytoprotective agent, reduces renal toxicity associated with repeated administration of cisplatin. Ototoxicity caused by cisplatin is unaffected by diuresis and is manifested by tinnitus and high-frequency hearing loss. Marked nausea and vomiting occur in almost all patients and usually can be controlled with 5HT₃ receptor antagonists, neurokinin (NK₁) receptor antagonists (e.g., aprepitant), and high-dose corticosteroids.

At higher doses or after multiple cycles of treatment, cisplatin causes a progressive peripheral motor and sensory neuropathy that may worsen after discontinuation of the drug and may be aggravated by subsequent or simultaneous treatment with taxanes or other neurotoxic drugs. Cisplatin causes mild-to-moderate myelosuppression, with transient
leukopenia and thrombocytopenia. Anemia may become prominent after multiple cycles of treatment. Electrolyte disturbances, including hypomagnesemia, hypocalcemia, hypokalemia, and hypophosphatemia, are common. Hypocalcemia and hypomagnesemia secondary to tubular damage and renal electrolyte wasting may produce tetany if untreated. Routine measurement of Mg²⁺ concentrations in plasma is recommended. Hyperuricemia, hemolytic anemia, and cardiac abnormalities are rare side effects. Anaphylactic-like reactions, characterized by facial edema, bronchoconstriction, tachycardia, and hypotension, may occur within minutes after administration and should be treated by intravenous injection of epinephrine and with corticosteroids or antihistamines. Cisplatin has been associated with the development of AML, usually 4 years or more after treatment.

**Carboplatin**

The mechanisms of action and resistance and the spectrum of clinical activity of carboplatin are similar to cisplatin. However, the two drugs differ significantly in their chemical, pharmacokinetic, and toxicological properties.

**ADME**

Because carboplatin is much less reactive than cisplatin, the majority of drug in plasma remains in its parent form, unbound to proteins. Most drug is eliminated via renal excretion, with a t½ of about 2 h. A small fraction of platinum binds irreversibly to plasma proteins and disappears slowly, with a t½ of 5 days or more.

**Therapeutic Uses**

Carboplatin and cisplatin are equally effective in the treatment of patients with suboptimally debulked ovarian cancer, non–small cell lung cancer, and extensive-stage small cell lung cancer; however, carboplatin may be less effective than cisplatin in the treatment of patients with germ cell, head and neck, and esophageal cancers. Carboplatin is an effective alternative for responsive tumors in patients unable to tolerate cisplatin because of impaired renal function, refractory nausea, significant hearing impairment, or neuropathy, but doses must be adjusted for renal function. In addition, it may be used in high-dose therapy with bone marrow or peripheral stem cell rescue. Carboplatin is administered as an intravenous infusion over at least 15 min and is given once every 21–28 days; the overall dose of carboplatin should be adjusted in proportion to the reduction in creatinine clearance for patients with CLCr < 60 mL/min and use the Calvert formula for adjustment (Calvert et al., 1989).

**Adverse Effects**

Carboplatin is relatively well tolerated clinically, causing less nausea, neurotoxicity, otoxicity, and nephrotoxicity than cisplatin. The dose-limiting toxicity of carboplatin is myelosuppression, primarily thrombocytopenia. It may cause a hypersensitivity reaction; in patients with a mild reaction, premedication, graded doses of drug, and more prolonged infusion lead to desensitization.

**Oxaliplatin**

**ADME**

Oxaliplatin has a short t½ in plasma, probably as a result of its rapid uptake by tissues and its reactivity; the initial t½ is about 17 min. No dose adjustment is required for hepatic dysfunction or for patients with a CLCr ≥ 20 mL/min.

**Therapeutic Uses**

Oxaliplatin exhibits a range of antitumor activity (colorectal and gastric cancer) that differs from other platinum agents. Oxaliplatin's effectiveness in colorectal cancer is perhaps due to its MMR- and HMG-independent effects. It also suppresses expression of TS, the target enzyme of 5FU. Oxaliplatin may be less effective than cisplatin in the treatment of patients with colorectal cancer.

---

**Adverse Effects**

The dose-limiting toxicity of oxaliplatin is peripheral neuropathy. An acute form, often triggered by exposure to cold liquids, manifests as paresthesias or dysesthesias in the upper and lower extremities, mouth, and throat. A second type relates to cumulative dose and has features similar to cisplatin neuropathy; 75% of patients receiving a cumulative dose of 1560 mg/m² experience some progressive sensory neurotoxicity, with dysesthesias, ataxia, and numbness of the extremities. Hematological toxicity is mild to moderate, except for rare immune-mediated cytopenias; nausea is well controlled with SHT receptor antagonists. Oxaliplatin may cause leukemia and pulmonary fibrosis months to years after administration. Oxaliplatin may cause an acute allergic response with urticaria, hypotension, and bronchoconstriction.

---

**II. Antimetabolites**

**Folic Acid Analogues**

Folic acid is an essential dietary factor that is converted by enzymatic reduction to FH₄, cofactors that provide methyl groups for the synthesis of precursors of DNA (thymidylate and purines) and RNA (purines) (Wilson et al., 2014). Folic acid analogues such as MTX interfere with FH₄ metabolism (Figure 66–5), reducing the cellular capacity for one-carbon transfer and methylation reactions in the synthesis of purine ribonucleotides and TMP, thereby inhibiting DNA replication.

---

**HISTORY Antifolate Chemotherapy**

Antifolate chemotherapy produced the first striking, although temporary, remissions in leukemia (Farber et al., 1948) and the first cure of a solid tumor, choriocarcinoma (Berlin et al., 1963). Interest in folate antagonists further increased with the development of curative combination therapy for childhood acute lymphocytic leukemia; in this therapy, MTX played a critical role in both systemic treatment and intrathecal therapy. Introduction of high-dose regimens with “rescue” of host toxicity by the reduced folate leucovorin (folinic acid, citrovorum factor, 5-formyl tetrahydrofolate, N⁵-formyl FH₄) further extended the effectiveness of this drug to both systemic and CNS lymphomas, osteogenic sarcoma, and leukemias. Recognition that MTX, an inhibitor of DHFR, also directly inhibits the folate-dependent enzymes of de novo purine synthesis and thymidine synthesis led to development of antifolate analogues that specifically target these other folate-dependent enzymes. New congeners have greater capacity for transport into tumor cells (pralatrexate) and exert their primary inhibitory effect on TS (ralitrexed), early steps in purine biosynthesis (lometrexol), or both (the multitargeted antifolate pemtrexed).

---

**Mechanism of Action**

The primary target of folic analogs, such as MTX, is the enzyme DHFR (see Figure 66–6). To function as a cofactor in one-carbon transfer reactions, folate must be reduced to FH₄. Inhibitors such as MTX, with a high affinity for DHFR (Kᵢ about 0.01–0.2 nM), cause partial depletion of N⁵,N¹₀ methylene FH₄ and N¹₀ formyl FH₄ cofactors that are required for the synthesis of thymidylate and purines. In addition, MTX, like cellular folates, undergoes addition of a series of polyglutamates (MTX-PGs) in both normal and tumor cells (Figure 66–5). These PGs constitute intracellular storage forms of folates and folate analogues that dramatically increase inhibitory potency of the analogue for additional sites, including TS and two early enzymes in the purine biosynthetic pathway. The FH₄ PGs that accumulate in cells behind the blocked DHFR reaction also act as inhibitors of TS and other enzymes (see Figure 66–6) (Allegra et al., 1987b).
**Selective Toxicity: Rescue**

As with most antimetabolites, MTX is only partially selective for tumor cells and kills rapidly dividing normal cells, such as those of the intestinal epithelium and bone marrow. Folate antagonists kill cells during the S phase of the cell cycle and are most effective when cells are proliferating rapidly. The toxic effects of MTX may be terminated by administering leucovorin, a fully reduced folate coenzyme that repletes the intracellular pool of FH₄ cofactors (see Figure 66–6).

**Cellular Entry and Retention**

Because folic acid and many of its analogues are polar, they cross the blood-brain barrier poorly and require specific transport mechanisms to enter mammalian cells. Three inward folate transport systems are found on mammalian cells:

1. A folate receptor, which has high affinity for folic acid but much lower ability to transport MTX and other analogues
2. The reduced folate transporter, the major transit protein for MTX, raltitrexed, pemetrexed, and most analogues
3. A transporter that is active at low pH

The reduced folate transporter is highly expressed in the hyperdiploid subtype of ALL, which has extreme sensitivity to MTX (Pui et al., 2004). Once in the cell, additional glutamyl residues are added to the molecule by the enzyme folylpolyglutamate synthetase. Because these higher PGs are strongly charged and cross cellular membranes poorly, polyglutamation serves as a mechanism of ion trapping within the cell. The polyglutamation may also account for the prolonged retention of MTX in chorionic epithelium (where it is a potent abortifacient); in tumors derived from this tissue, such as choriocarcinoma cells; and in normal tissues subject to cumulative drug toxicity, such as liver. Polyglutamyl folates and analogues have substantially greater affinity than the monoglutamate form for folate-dependent enzymes that are required for purine and thymidylate synthesis and have at least equal affinity for DHFR.

**Newer Congeners**

New folate antagonists that are better substrates for the reduced folate carrier have been identified. In efforts to bypass the obligatory membrane transport system and to facilitate penetration of the blood-brain barrier, lipid-soluble folate antagonists also have been synthesized. Trimetrexate, a lipid-soluble analogue that lacks a terminal glutamate, has modest

---

**Figure 66–5**  Folic acid, metabolic intermediates, and MTX. The shading identifies common structural features and areas of modification. Yellow highlights indicate sites modified by DHFR to FH₃ (DHF) and to FH₄ (THF); red atoms and bonds indicate metabolic intermediates that serve as single-carbon donors (see pathways in Figure 66–6).

**De novo purine synthesis**

AICAR transformylase provides the C8 and AICAR transformylase the C2 in the purine ring biosynthesis (see Figure 66–1 for numbering of purine ring atoms). AICAR, aminoimidazole carboxamide; dUMP, deoxyuridine monophosphate; FH₄Glu₉, dihydrofolate polyglutamate; FH₂Glu₉, tetrahydrofolate polyglutamate; GAR, glycaminide ribonucleotide; IMP, inosine monophosphate; PRPP, 5-phosphoribosyl-1-pyrophosphate; TMP, thymidine monophosphate.

---

**Figure 66–6**  Folate metabolism and the actions of 5FU, MTX, and MTX polyglutamates. A. Thymidylate synthesis (for composition of folates, see Figure 66–5). B. De novo purine synthesis. GAR transformylase provides the C8 and AICAR transformylase the C2 in the purine ring biosynthesis (see Figure 66–1 for numbering of purine ring atoms). AICAR, aminoimidazole carboxamide; dUMP, deoxyuridine monophosphate; FH₄Glu₉, dihydrofolate polyglutamate; FH₂Glu₉, tetrahydrofolate polyglutamate; GAR, glycaminide ribonucleotide; IMP, inosine monophosphate; PRPP, 5-phosphoribosyl-1-pyrophosphate; TMP, thymidine monophosphate.
Mechanisms of Resistance to Antifolates

Resistance to MTX can involve alterations in each known step in MTX action, including:

- Impaired transport of MTX into cells
- Production of altered forms of DHFR that have decreased affinity for the inhibitor
- Increased concentrations of intracellular DHFR through gene amplification or altered gene regulation
- Decreased ability to synthesize MTX-PGs
- Increased expression of a drug efflux transporter of the MRP class (see Chapter 5)

The DHFR levels in leukemic cells increase within 24 h after treatment of patients with MTX, probably as a result of induction of DHFR synthesis. Unbound DHFR protein may bind to its own message and reduce its translation. With longer periods of drug exposure, tumor cell populations emerge that contain markedly increased levels of DHFR. These cells contain multiple gene copies of DHFR either in mitotically unstable double-minute chromosomes (extrachromosomal elements) or in stably integrated, homogeneously staining chromosomal regions or amplicons (Schimke et al., 1978). Similar gene amplification target proteins have been implicated in the resistance to other antitumor agents, including SFU and pentostatin (2′-deoxycytosine) and observed in patients with lung cancer (Curt et al., 1985).

High doses of MTX may permit entry of the drug into transport-defective cells and may permit the intracellular accumulation of MTX in concentrations that inactivate high levels of DHFR. The understanding of resistance to pemetrexed is incomplete. In various cell lines, resistance seems to arise from loss of influx transport, TS amplification, changes in purine biosynthetic pathways, or loss of polyglutamation.

ADME

Methotrexate is readily absorbed from the GI tract at doses of less than 25 mg/m²; larger doses are absorbed incompletely and are routinely administered intravenously. After intravenous administration, the drug disappears from plasma in a triphasic fashion. The rapid distribution phase is followed by a second phase, which reflects renal clearance (t½ of about 2–3 h). A third phase has a t½ of about 8–10 h. This terminal phase of disappearance, if prolonged by renal failure, may be responsible for major toxic effects of the drug on the bone marrow, GI epithelium, and skin. Distribution of MTX into body spaces, such as the pleural or peritoneal cavity, occurs slowly. However, if such spaces are expanded (e.g., by ascites or pleural effusion), they may act as a site of storage and slow release of the drug, resulting in prolonged elevation of plasma concentrations and more severe bone marrow toxicity.

Approximately 50% of MTX binds to plasma proteins and may be displaced from plasma albumin by myriad drugs, including sulfonamides, salicylates, tetracycline, chloramphenicol, and phenytoin; caution should be used if these drugs are given concomitantly. Up to 90% of a given dose of MTX is excreted unchanged in the urine, mostly within the first 8–12 h. Metabolism of MTX usually is minimal. After high doses, however, metabolites are readily detectable; these include 7-hydroxy-MTX, which is potentially nephrotoxic. Renal excretion of MTX occurs through a combination of glomerular filtration and active tubular secretion. Therefore, the concurrent use of drugs that reduce renal blood flow (e.g., NSAIDs), that are nephrotoxic (e.g., cisplatin), or that are weak organic acids (e.g., aspirin) can delay drug excretion and lead to severe myelosuppression. In patients with renal insufficiency, the dose should be adjusted in proportion to decreases in renal function, and high-dose regimens should be avoided. Concentrations of MTX in CSF are only 3% of those in the systemic circulation at steady state; hence, neoplastic cells in the CNS probably are not killed by standard dosage regimens. When high doses of MTX are given, cytotoxic concentrations of MTX reach the CNS beyond the blood-brain barrier. MTX is retained in the form of PGs for long periods (e.g., weeks in the kidneys, several months in the liver).

Pharmacogenetics may influence the response to antifolates and their toxicity. The C677T substitution in methylenetetrahydrofolate reductase reduces the activity of the enzyme that generates N5–10 methylene FH₄, the cofactor for TS, and thereby increases MTX toxicity (Pullarkat et al., 2001). The presence of this polymorphism in leukemic cells confers increased sensitivity to MTX and might also modulate the toxicity and therapeutic effect of pemetrexed, a predominant TS inhibitor. Likewise, polymorphisms in the promoter region of TS affect its expression and, by altering the intracellular levels of TS, modulate the response and toxicity of both antifolates and fluoropyrimidines (Pui et al., 2004).

Therapeutic Uses

Methotrexate is a critical drug in the management of childhood ALL. High-dose MTX is of great value in remission induction and consolidation and in the maintenance of remissions in this highly curable disease. A 6- to 24-h infusion of relatively large doses of MTX may be employed every 2–4 weeks but only when leucovorin rescue follows within 24 h of the MTX infusion. For maintenance therapy, it is administered at a lower dose, orally every week. Outcome of treatment in children correlates inversely with the rate of drug clearance. During MTX infusion, high steady-state levels are associated with a lower leukemia relapse rate. Methotrexate is of limited value in adults with AML, except for treatment and prevention of leukemic meningitis.

The intrathecal administration of MTX has been employed for treatment or prophylaxis of meningeal leukemia or lymphoma and for treatment of meningeal carcinomatosis. This route of administration achieves high concentrations of MTX in the CSF and also is effective in patients whose systemic disease has become resistant to MTX. The treatment is repeated every 4 days until malignant cells no longer are evident in the CSF. Leucovorin may be administered to counteract the potential toxicity of MTX that escapes into the systemic circulation, although this generally is not necessary. Because MTX administered into the lumbar space distributes poorly over the cerebral convexities, the drug may be given via an intraventricular catheter system in the treatment of active intrathecal disease. MTX is of established value in chorioncarcinoma and related trophoblastic tumors of women; cure is achieved in about 75% of advanced cases treated sequentially with MTX and dactinomycin and in more than 90% when early diagnosis is made. For chorioncarcinoma, MTX is administered intramuscularly every other day for four doses, alternating with leucovorin. Courses are repeated at 3-week intervals, toxicity permitting, and urinary β-human chorionic gonadotropin titers are used as a guide for persistence of disease.

Beneficial effects also are observed in the combination therapy of Burkitt and other non-Hodgkin lymphomas. MTX is a component of regimens for carcinomas of the breast, head and neck, ovary, and bladder. HDM-L is a standard agent for adjuvant therapy of osteosarcoma and produces a high complete response rate in CNS lymphomas. The administration
CHAPTER 66
CYTOTOXIC DRUGS

B12 deficiency. These small doses of folate and B12 do not compromise the contribution to their cytotoxicity and their capacity to induce differentiation. Vitamin B12 (1 mg) with the first dose of pemetrexed to correct possible elimination by concurrent administration of low dosages of folic acid, seen especially in patients with preexisting homocystinemia, largely is. Amethasone, 4 mg twice daily on days –1, 0, and +1, markedly diminishes of a prominent erythematous and pruritic rash in 40% of patients. Dex -thecal administration of MTX often causes meningismus and an inflammatory response in the CSF. Seizures, coma, and death may occur rarely. The primary toxicities of antifolates are on the bone marrow and the intestinal epithelium. Patients may be at risk for spontaneous hemorrhage or life-threatening infection and may require prophylactic transfusion of platelets and broad-spectrum antibiotics if febrile. Side effects usually reverse completely within 2 weeks, but prolonged myelosuppression may occur in patients with compromised renal function who have delayed drug excretion. The dosage of MTX (and likely pemetrexed) must be reduced in patients with compromised renal function who have delayed drug excretion. The dosage of MTX (and likely pemetrexed) must be reduced in patients with compromised renal function who have delayed drug excretion. Adequate hydration and alkalinization of urine pH are required prior to drug administration. If MTX values measured 48 h after drug administration are 1 μM or higher, higher doses (100 mg/m2) of leucovorin must be given until the plasma concentration of MTX falls to less than 50 nM. With appropriate hydration and urine alkalization, and in patients with normal renal function, the incidence of nephrotoxicity following HDM-L is less than 2%. In patients who become oliguric, intermittent hemodialysis is ineffective in reducing MTX levels. Continuous-flow hemodialysis can eliminate MTX at about 50% of the clearance rate in patients with intact renal function. Alternatively, a MTX-cleaving enzyme, glucaacidase, is FDA approved for the treatment of MTX toxicity. Glucarpidase is a recombinant bacterial carboxypeptidase G2 that converts MTX into glutamate and 2,4-diamino-N(10)-methylpteroyl acid. These metabolites are less toxic and are excreted by the liver. MTX concentrations in plasma fall by 99% or more within 5–15 min following enzyme administration. However, systemically administered carboxypeptidase G2 has little effect on MTX levels in the CSF.

Modification of Base and deoxyribonucleoside analogues. Yellow ellipses indicate sites modified to create antimetabolites. Specific substitutions are noted in red for each drug. Modifications occur in the base ring systems, in their amino or hydroxyl side groups, and in the deoxyribose sugar found in deoxyribonucleosides. See structures in Figure 66–8.

Pyrimidine Analogue

The pyrimidine antimetabolites encompass a diverse group of drugs that inhibit RNA and DNA function. The fluoropyrimidines and certain purine analogues (6MP and 6TG) inhibit the synthesis of essential precursors of DNA. Others, such as the cytidine and adenosine nucleoside analogues, become incorporated into DNA and block its further elongation and function (Wilson et al., 2014). Other inhibitory effects of these analogues may contribute to their cytotoxicity and their capacity to induce differentiation.

Cellular Actions of Pyrimidine Antimetabolites

Four bases (Figure 66–7) form DNA: two pyrimidines (thymine and cytosine) and two purines (guanine and adenine). RNA differs in that it incorporates uracil instead of thymine as one of its bases. Strategies for inhibiting DNA synthesis are based on the ability to create analogues of these precursors that readily enter tumor cells and become activated intracellularly. As an example, the pyrimidine analog 5FU is converted to an FDUMP, which in turn blocks TS, an enzyme required for the physiologic conversion of dUMP to dTMP, a component of DNA (see Figure 66–6). Other analogues incorporate into DNA itself and thereby block its function (Wilson et al., 2014).

Cells can make the purine and pyrimidine bases de novo and convert them to their active triphosphates (dNTPs), providing substrates for DNA polymerase. Alternatively, cells can salvage free bases or their deoxynucleosides from the bloodstream. Thus, cells can take up uracil, guanine, and their analogues and convert them to (deoxy)nucleotides by the addition of deoxyribose and phosphate groups. Antitumor analogues of these bases (5FU, 6TG) can be formulated as simple substituted bases. Other bases, including cytosine, thymine, and adenine, and their analogues can only be used as deoxynucleosides, which are readily transported into cells and activated to deoxynucleotides by intracellular kinases. Thus, cytarabine (cytosine arabinoside; Ara-C), gemcitabine, 5-azacytidine, and adenosine analogues (cladribine) (Figures 66–7 and 66–8) are nucleosides readily taken up by cells, converted to nucleotides, and incorporated into DNA.

Fludarabine phosphate, a nucleotide, is dephosphorylated rapidly in plasma, releasing the nucleoside that is readily taken up by cells. Analogues may differ from the physiological bases in a variety of ways: by altering in the purine or pyrimidine ring; by altering the sugar attached
to the base, in the arabinoside, Ara-C, or by altering both the base and sugar, as in fludarabine phosphate (see Figure 66–7). These alterations produce inhibitory effects on vital enzymatic pathways and prevent DNA synthesis.

**Fluorouracil, Fluorouridine, Capecitabine**

Fluorouracil is available as 5FU, as the derivative FUdR (not often used in clinical practice), and as a prodrug, capecitabine, which is ultimately converted to 5FU.

**Mechanisms of Action**

5-Fluorouracil requires enzymatic conversion (ribosylation and phosphorylation) to the nucleotide form to exert its cytotoxic activity. As the triphosphate FUTP, the drug is incorporated into RNA. Alternative reactions can produce the deoxy derivative FdUMP; FdUMP inhibits TS and blocks the synthesis of dTTP, a necessary constituent of DNA (Figure 66–6). The folate cofactor, 5,10-methylene FH4, and FdUMP form a covalently bound ternary complex with TS. The physiological complex of TS-folate-dUMP progresses to the synthesis of thymidylate by transfer of the methylene group and two hydrogen atoms from folate to dUMP, but this reaction is blocked in the inhibited complex of TS-FdUMP-folate by the stability of the fluorine carbon bond on FdUMP; sustained inhibition of the enzyme results.

5-Fluorouracil is incorporated into both RNA and DNA. In 5FU-treated cells, both FdUTP and dUTP (which accumulates behind the blocked TS reaction) incorporate into DNA in place of the depleted physiological TTP. Presumably, such incorporation into DNA calls into action the excision-repair process, which can lead to DNA strand breakage because DNA repair requires TTP, which is lacking as a result of TS inhibition. 5FU incorporation into RNA also causes toxicity as the result of major effects on both the processing and the functions of RNA.

**Mechanisms of Resistance**

Resistance to the cytotoxic effects of 5FU or FUdR has been ascribed to loss or decreased activity of the enzymes necessary for activation of 5FU; amplification of TS; mutation of TS to a form that is not inhibited by FdUMP; and high levels of the degradative enzymes dihydouracil dehydrogenase and thymidine phosphorylase. TS levels are finely controlled by an autoregulatory feedback mechanism wherein the unbound enzyme interacts with and inhibits the translational efficiency of its own mRNA, which provides for the rapid TS modulation needed for cellular division. When TS is bound to FdUMP, inhibition of translation is relieved and levels of free TS rise, restoring thymidylate synthesis. Thus, TS autoregulation may be an important mechanism by which malignant cells become insensitive to the effects of 5FU.

**Combination With Leucovorin**

Some malignant cells appear to have insufficient concentrations of 5,10-methylene FH4, and thus cannot form maximal levels of the inhibited ternary complex with TS. Addition of exogenous folate in the form of leucovorin increases formation of the complex and enhances responses to 5FU. A number of other agents have been combined with 5FU in attempts to enhance the cytotoxic activity through biochemical modulation. MTX, by inhibiting purine synthesis and increasing cellular pools of PRPP, enhances the activation of 5FU and increases antitumor activity of 5FU when given prior to but not following 5FU. The combination of cisplatin and 5FU has yielded impressive responses in tumors of the upper aerodigestive tract, but the molecular basis of their interaction is unclear. A combination with oxaliplatin, which downregulates TS expression, is commonly used with 5FU and leucovorin for treating patients with metastatic colorectal cancer; the combination is abbreviated as FOLFOX. Addition of irinotecan (see discussion that follows) is abbreviated as FOLFIRINOX and used in the treatment of patients with colorectal or pancreatic cancer.

**ADME**

5-Fluorouracil is administered parenterally because absorption after oral ingestion of the drug is unpredictable and incomplete. 5FU is inactivated
by reduction of the pyrimidine ring in a reaction carried out by DPD, which is found in liver, intestinal mucosa, tumor cells, and other tissues. Inherited deficiency of this enzyme leads to greatly increased sensitivity to the drug (Milano et al., 1999). DPD deficiency can be detected by either enzymatic or molecular assays using peripheral white blood cells or by determining the plasma ratio of 5FU to its metabolite, 5-fluoro-5,6-dihydropuracil.

Plasma clearance is rapid (t1/2 about 20–30 min). Only 5%–10% of a single intravenous dose of 5FU is excreted intact in the urine. The dose does not have to be modified in patients with hepatic dysfunction, presumably because of sufficient degradation of the drug at extrahepatic sites. 5FU enters the CSF in minimal amounts.

**Therapeutic Uses**

**5-Fluorouracil.** 5-Fluorouracil produces partial responses in 10%–20% of patients with metastatic colon carcinomas, upper GI tract carcinomas, and breast carcinomas but rarely is used as a single agent. 5FU in combination with leucovorin and oxaliplatin or irinotecan (FOLFIRINOX) in adjuvant therapy is associated with a survival advantage for patients with colorectal cancers. For average-risk patients in good nutritional status with adequate hematopoietic function, the dosage regimen is often used. 5FU may employ doses for 5 days, repeated in monthly cycles. When used with leucovorin, doses of daily 5FU for 5 days must be reduced because of mucositis and diarrhea. 5FU is increasingly used as a biweekly infusion, a schedule that has less overall toxicity as well as superior response rates and progression-free survival for patients with metastatic colon cancer.

**Floxuridine.** Fluorodeoxyuridine is converted directly toFdUMP by thymidine kinase. The drug is administered primarily by continuous infusion into the hepatic artery for treatment of patients with metastatic carcinoma of the colon or following resection of hepatic metastases; the response rate of intrahepatic infusion (40%–50%) is twice that of intravenous administration. Intrahepatic arterial infusion for 14–21 days causes minimal systemic toxicity; however, there is a significant risk of biliary sclerosis if this route is used for multiple cycles of therapy. Treatment should be discontinued at the earliest manifestation of toxicity (usually stomatitis or diarrhea) because the maximal effects of bone marrow suppression and gut toxicity will not be evident until days 7–14.

**Capecitabine.** Capecitabine, an orally administered prodrug of 5FU, is approved for the treatment of patients with (1) metastatic breast cancer who have not responded to a regimen of paclitaxel and an anthracycline; (2) metastatic breast cancer when used in combination with docetaxel in patients who have had a prior anthracycline-containing regimen; and (3) metastatic colorectal cancer.

The recommended dosage is given in two divided doses with food, for 2 weeks, followed by a rest period of 1 week. Capecitabine is well absorbed orally. It is rapidly deesterified and deaminated, yielding high plasma concentrations of an inactive prodrug 5′-dFdU, which disappears with a t1/2 of about 1 h. The conversion of 5′-dFdU to 5FU by thymidine phosphorylase occurs in liver tissues, peripheral tissues, and tumors. 5FU levels are less than 10% of those of 5′-dFdU, reaching a maximum of 0.3 μg/mL or 1 μM at 2 h. Liver dysfunction delays the conversion of the parent compound to 5′-dFdU and 5FU, but there is no consistent effect on toxicity.

**Combination Therapy.** Higher response rates are seen when 5FU or capecitabine is used in combination with other agents (e.g., with cisplatin in head and neck cancer, with oxaliplatin or irinotecan in colon cancer). The combination of 5FU and oxaliplatin or irinotecan has become the standard first-line treatment of patients with metastatic colorectal cancer (FOLFIRINOX). The use of 5FU in combination regimens has improved survival in the adjuvant treatment of breast cancer and, with oxaliplatin and leucovorin, of colorectal cancer. 5FU also is a potent radiation sensitizer. Beneficial effects have been reported when combined with irradiation as primary treatment of patients with locally advanced cancers of the esophagus, stomach, pancreas, cervix, anus, and head and neck. 5FU is effective in the topical treatment of premalignant keratoses of the skin and multiple superficial basal cell carcinomas.

**Adverse Effects**

The clinical manifestations of toxicity caused by 5FU and floxuridine are similar. The earliest untoward symptoms during a course of therapy are anorexia and nausea, followed by stomatitis and diarrhea, reliable warning signs that a sufficient dose has been administered. Mucosal ulceraions occur throughout the GI tract and may lead to fulminant diarrhea, shock, and death, particularly in patients who are DPD deficient. The major toxic effects of bolus-dose regimens result from the myelosuppressive action of 5FU. The nadir of leukopenia usually occurs 9–14 days after the first injection of drug. Thrombocytopenia and anemia also may occur, as may loss of hair (occasionally progressing to total alopecia), nail changes, dermatitis, and increased pigmentation and atrophy of the skin. Hand-foot syndrome, a particularly prominent adverse effect of capecitabine, consists of erythema, desquamation, pain, and sensitivity to touch of the palms and soles. Acute chest pain with evidence of ischemia in the electrocardiogram may result from coronary artery vasospasms during or shortly after 5FU infusion. In general, myelosuppression, mucositis, and diarrhea occur less often with infusional than with bolus regimens, while hand-foot syndrome occurs more often with infusional than with bolus regimens. The significant risk of toxicity with fluoropyrimidines requires close supervision by physicians familiar with the drug’s effects and possible hazards. Capecitabine causes a similar spectrum of toxicities as 5FU (diarrhea, myelosuppression), but the hand-foot syndrome occurs more frequently and may require dose reduction or cessation of therapy.

**Trifluridine**

Trifluridine is a trifluoro nucleoside analogue of FUdR (see Figure 66–8). It is used in eye drops for the treatment of HSV and in a fixed combination with tipiracil, a thymidine phosphorylase inhibitor, for the treatment of patients with metastatic colorectal cancers who have previously received other standard combination treatments that included FOLFIRINOX. Trifluridine and tipiracil are formulated together in a single tablet with tipiracil added to prevent rapid breakdown of trifluridine. The trifluridine mechanism of action mimics that of 5FU (Davidson et al., 2016).

**Cytidine Analogues**

Cytarabine (Cytosine Arabinoside; Ara-C) Cytarabine is the most important antimetabolite used in the therapy of AML; it is the single most effective agent for induction of remission in this disease.

**Mechanisms of Action**

Cytarabine is an analogue of 2′-deoxyctydine; the 2′-hydroxyl in a position trans to the 3′-hydroxyl of the sugar (see Figures 66–7 and 66–8) hinders rotation of the pyrimidine base around the nucleoside bond and interferes with base pairing. The drug enters cells via ENT1 (or SLC29A1). It is then converted to its active form, the 5′-monophosphate ribonucleotide, by dCK, an enzyme that shows polymorphic expression amongst patients (see discussion that follows). Ara-CMP then reacts with deoxy-nucleoside kinases to form diphosphate and triphosphates (Ara-CDP and Ara-CTP). Ara-CTP competes with dCTP for incorporation into DNA by DNA polymerases. The incorporated Ara-CMP residue is a potent inhibitor of DNA polymerase, in both replication and repair synthesis, and blocks the further elongation of the nascent DNA molecule. If DNA breaks are not repaired, apoptosis ensues. Ara-C cytototoxicity correlates with the total Ara-C incorporated into DNA; incorporation of about 5 molecules of Ara-C per 107 bases of DNA decreases cellular clonogenicity by about 50% (Kufe et al., 1984).

In infants and adults with ALL and t(4;11) MLL translocation, high-dose Ara-C is particularly effective; in these patients, the nucleoside transporter ENT1 is highly expressed, and its expression correlates with sensitivity to Ara-C (Pui et al., 2004). At extracellular drug concentrations greater than 10μg, repeated in monthly cycles with high-dose Ara-C, the nucleoside transporter no longer limits drug accumulation, and intracellular metabolism to a triphosphate becomes rate limiting. Patients with particular...
subtypes of AML derive benefit from high-dose Ara-C treatment; these types include t(8;21), inv(16), (t;9;16), and del(16). Approximately 20% of patients with AML have leukemic cells with a KRAS mutation, and these patients seem to derive greater benefit from high-dose Ara-C regimens than do patients with wild-type KRAS.

**Mechanisms of Resistance**

Response to Ara-C is strongly influenced by the relative activities of anabolic and catabolic enzymes that determine the proportion of drug converted to Ara-CTP. The rate-limiting activating enzyme dCK produces Ara-CMP. It is opposed by the degradative enzyme, cytidine deaminase, which converts Ara-C to a nontoxic metabolite, Ara-U. Cytidine deaminase activity is high in many normal tissues, including intestinal mucosa, liver, and neutrophils, but lower in AML cells and other human tumors. A second degradative enzyme, dCMP deaminase, converts Ara-CMP to the inactive metabolite Ara-UMP. Increased synthesis and retention of Ara-C in leukemic cells lead to a longer duration of complete remission in patients with AML. The capacity of cells to transport Ara-C also may affect response. Clinical studies have implicated a loss of dCK as the primary mechanism of resistance to Ara-C in AML.

**ADME**

Due to the presence of high concentrations of cytidine deaminase in the GI mucosa and liver, only about 20% of the drug reaches the circulation after oral Ara-C administration; thus, the drug must be given intravenously. Peak concentrations of 2–50 μM are measurable in plasma after intravenous injection of 30–300 mg/m² but fall rapidly (τ₁/₂ = 10 min). Less than 10% of the injected dose is excreted unchanged in the urine within 12–24 h; most appears as the inactive deaminated product, Ara-U. Higher concentrations of Ara-C are found in CSF after continuous infusion than after rapid intravenous injection but are 10% or less of concentrations in plasma. After intrathecal administration of the drug at a dose of 50 mg/m², deamination proceeds slowly, with a τ₁/₂ of 3–4 h, and peak concentrations of 1–2 μM are achieved. CSF concentrations remain above the threshold for cytotoxicity (0.4 μM) for 24 h or longer. A depot liposomal formulation of Ara-C provides sustained release into the CSF. After a standard dose, liposomal Ara-C remains above cytotoxic levels for an average of 12 days, thus avoiding the need for frequent lumbar punctures.

**Therapeutic Uses**

Continuous inhibition of DNA synthesis for a duration equivalent to at least one cell cycle or 24 h is necessary to expose most tumor cells during the S phase of the cell cycle. The optimal interval between bolus doses of Ara-C is about 8–12 h, a schedule that maintains intracellular concentrations of Ara-CTP at inhibitory levels during a multiday cycle of treatment. In general, children tolerate higher doses than adults. The intrathecal administration of liposomal cytarabine every 2 weeks seems equally effective as the regimen every 4 days with the standard drug. Ara-C is indicated for induction and maintenance of remission in AML and is useful in the treatment of patients with other leukemias, such as ALL, CML in the blast phase, APL, and high-grade lymphomas. Because drug concentration in plasma rapidly falls below the level needed to saturate transport and intracellular activation, clinicians have employed high-dose regimens every 12 h for 3–4 days to achieve 20–50 times higher serum levels, with improved results in remission induction and consolidation for AML. Injection of the liposomal formulation is indicated for the intrathecal treatment of lymphomatous meningitis.

**Adverse Effects**

Cytarabine is myelosuppressive and can produce acute, severe leukopenia, thrombocytopenia, and anemia with striking megaloblastic changes. Other toxic manifestations include GI disturbances, stomatitis, conjunctivitis, reversible hepatic enzyme elevations, noncardiogenic pulmonary edema, and dermatitis. The onset of dyspnea, fever, and pulmonary infiltrates on chest computed tomographic scans may follow 1–2 weeks after high-dose Ara-C and may be fatal in 10%–20% of patients, especially in patients being treated for relapsed leukemia. No specific therapy, other than Ara-C discontinuation, is indicated. Intrathecal Ara-C, either the free drug or the liposomal preparation, may cause arachnoiditis, seizures, delirium, myelopathy, or coma, especially if given concomitantly with systemic high-dose MTX or systemic Ara-C. Cerebellar toxicity, manifesting as ataxia and slurred speech, and cerebral toxicity (seizures, dementia, and coma) may follow intrathecal administration or high-dose systemic administration, especially in patients older than 40 years or patients with poor renal function.

**Azacitidine (5-Azacytidine); Decitabine**

5-Azacytidine (Figure 66–7) and decitabine (2′-deoxy-5-azacytidine; Figure 66–8) have antileukemic activity and induce differentiation by inhibiting DNA cytosine methyltransferase activity. Both drugs are approved for treatment of myelodysplasia, for which they induce normalization of bone marrow in 15%–20% of patients and reduce the transfusion requirement in one-third of patients. 5-Azacytidine improves survival.

**Mechanism of Action**

Theaza-nucleosides enter cells by ENT1 (SLC29A1), the major route; CNT1 (SLC28A1); and a nucleobase transporter (SLC29A1; the major route); CNT1 (SLC28A1); and a nucleobase transporter. 5-Azacytidine (Figure 66–7) and decitabine (2′-deoxy-5-azacytidine; Figure 66–8) have antileukemic activity and induce differentiation by inhibiting DNA cytosine methyltransferase activity. Both drugs are approved for treatment of myelodysplasia, for which they induce normalization of bone marrow in 15%–20% of patients and reduce the transfusion requirement in one-third of patients. 5-Azacytidine improves survival.

**Therapeutic Use**

The usual treatment regimen for 5-azacytidine in patients with MDS is daily for 7 days every 28 days, while decitabine is given intravenously every day for 5 days every 4 weeks. Best responses may become apparent only after two to five courses of treatment.

**Adverse Effects**

The major toxicities of theaza-nucleosides include myelosuppression and mild GI symptoms. 5-Azacytidine produces severe nausea and vomiting when given intravenously in large doses (150–200 mg/m²/d for 5 days).

**Gemcitabine**

Gemcitabine, a difluoro analogue of deoxycytidine (dFdC; see Figure 66–8), is used for patients with metastatic pancreatic; non-squamous, non–small cell lung; ovarian; and bladder cancer.

**Mechanism of Action**

Gemcitabine enters cells via three distinct nucleoside transporters: ENT1 (SLC29A1; the major route); CNT1 (SLC28A1); and a nucleobase transporter found in malignant mesothelioma cells. Intracellularly, dCK phosphorylates gemcitabine to the monophosphate (dFdCMP), which is converted to di- and triphosphates (dFdCDP and dFdCTP, respectively). Although gemcitabine's anabolism and effects on DNA in general mimic those of cytarabine, there are distinct differences in kinetics of inhibition, additional enzymatic sites of action, different effects of incorporation into DNA, and a distinct spectrum of clinical activity. Unlike that of cytarabine, the cytotoxicity of gemcitabine is not confined to the S phase of the cell cycle. The cytotoxic activity may reflect several actions on DNA synthesis. dFdCTP competes with dCTP as a weak inhibitor of DNA polymerase. dFdCDP is a stoichiometric inhibitor of RNR, resulting in depletion of deoxyribonucleotide pools necessary for DNA synthesis. Incorporation of dFdCTP into DNA causes DNA strand termination (Heinemann et al., 1988) and appears resistant to repair. The capacity of cells to incorporate dFdCTP into DNA is critical for gemcitabine-induced apoptosis. Gemcitabine is inactivated by cytidine deaminase, which is found both in tumor cells and throughout the body.

**ADME**

Gemcitabine is administered as an intravenous infusion. The pharmacokinetics of the parent compound are largely determined by deamination in liver, plasma, and other organs, and the predominant urinary elimination product is dFdU. In patients with significant renal dysfunction, dFdU and
its triphosphate accumulate to high and potentially toxic levels. Gemcitabine has a short plasma t½ (~15 min); women and elderly patients clear the drug more slowly.

**Therapeutic Uses**
The standard dosing schedule for gemcitabine is an intravenous infusion on days 1, 8, and 15 of each 21- to 28-day cycle, depending on the indication. Conversion of gemcitabine to dFdCMP by dCK is saturated at infusion rates of about 10 mg/m²/min. To increase dFdCTP formation, the duration of infusion at this maximum concentration has been extended to 100–150 min at a fixed rate of 10 mg/min. The 150-min infusion produces a higher level of dFdCTP within peripheral blood mononuclear cells and increases the degree of myelosuppression. The inhibition of DNA repair by gemcitabine may increase cytotoxicity of other agents, particularly platinum compounds, and with radiation therapy.

**Adverse Effects**
The principal toxicity is myelosuppression. Longer duration infusions lead to greater myelosuppression and hepatic toxicity. Nonhematological toxicities include a flu-like syndrome, asthenia, and rarely a posterior leukoencephalopathy syndrome. Mild, reversible elevation in liver transaminases may occur in 40% or more of patients. Interstitial pneumonitis, at times progressing to ARDS, may occur within the first two cycles of treatment and usually responds to corticosteroids. Rarely, patients treated for many months may develop a slowly progressive hemolytic uremic syndrome, necessitating drug discontinuation. Gemcitabine is a very potent radiosensitizer and should not be used with radiotherapy.

### Purine Anallogues

The pioneering studies of Hitchings and Elion identified analogues of naturally occurring purine bases with antileukemic and immunosuppressant properties. Figure 66–9 shows structural formulas of several purine analogues, with adenosine for comparison. Other purine analogues that have valuable roles in leukemia and lymphoid malignancies include cladribine (standard therapy of hairy cell leukemia), fludarabine phosphate (standard treatment of CLL), nelarabine (pediatric ALL), and clofarabine (T-cell leukemia/lymphoma). The apparent selectivity of these agents may relate to their effective uptake, activation, and apoptotic effects in lymphoid tissue.

#### 6-Thiopurine Anallogues

6-Mercaptopurine and 6TG are approved agents for human leukemias and function as analogues of the natural purines hypoxanthine and guanine. The substitution of sulfur for oxygen on C6 of the purine ring creates compounds that are readily transported into cells, including activated malignant cells. Nucleotides formed from 6MP and 6TG inhibit de novo purine synthesis and also become incorporated into nucleic acids (Figure 51–5).

**Mechanism of Action**

Hypoxanthine guanine phosphoribosyltransferase converts 6TG and 6MP to the ribonucleotides 6-thioguanosine monophosphate (6TGMP) and 6-thioinosine monophosphate (6IMP). Because T-IMP is a poor substrate for guanylyl kinase (the enzyme that converts GMP to GDP), T-IMP accumulates intracellularly. T-IMP inhibits the new formation of ribosyl-5'-phosphate, as well as conversion of IMP to adenine and guanine nucleotides. The most important point of attack seems to be the reaction of glutamine and PRPP to form ribosyl-5'-phosphate, the first committed step in the de novo pathway. 6TG nucleotide is incorporated into DNA, where it induces strand breaks and base mispairing.

**Mechanisms of Resistance**

The most common mechanism of 6MP resistance observed in vitro is deficiency or complete lack of the activating enzyme HPRT or increased alkaline phosphatase activity. Other mechanisms for resistance include:

- decreased drug uptake or increased efflux due to active transporters;
- alteration in allosteric inhibition of ribosylamine 5'-phosphate synthase; and
- impaired recognition of DNA breaks and mismatches due to loss of a component (MSH6) of MMR system (Karran and Attard, 2008).

**ADME and Toxicity**

Absorption of oral mercaptopurine is incomplete (10%–50%); the drug is subject to first-pass metabolism by xanthine oxidase in the liver. Food or oral antibiotics decrease absorption. Oral bioavailability is increased when mercaptopurine is combined with high-dose MTX. After an intravenous dose, the t½ of the drug is about 50 min in adults due to rapid metabolic degradation by xanthine oxidase and by TPMT. Restricted brain distribution of mercaptopurine results from an efficient efflux transport system in the blood-brain barrier. In addition to the HPRT-catalyzed anabolism of mercaptopurine, there are two other pathways for its metabolism. The first involves methylation of the sulfhydryl group and subsequent oxidation of the methylated derivatives. Activity of the enzyme TPMT reflects the inheritance of polymorphic alleles; up to 15% of the Caucasian population has decreased enzyme activity. Low levels of erythrocyte TPMT activity are associated with increased drug toxicity in individual patients and a lower risk of relapse. In patients with autoimmune disease treated with mercaptopurine, those with polymorphic alleles may experience bone marrow aplasia and life-threatening toxicity. Testing for these polymorphisms prior to treatment is recommended in this patient population.

A relatively large percentage of the administered sulfur appears in the urine as inorganic sulfate. The second major pathway for 6MP metabolism involves its oxidation by xanthine oxidase to 6-thiourate, an inactive metabolite. Oral doses of 6MP should be reduced by 75% in patients receiving the xanthine oxidase inhibitor allopurinol; no dose adjustment is required for intravenous dosing.

**Therapeutic Uses**

In the maintenance therapy of ALL, an initial daily oral dose of 6MP is adjusted according to white blood cell and platelet counts. The combination of MTX and 6MP appears to be synergistic. By inhibiting the earliest steps in purine synthesis, MTX elevates the intracellular concentration of PRPP, a cofactor required for 6MP activation.
Adverse Effects
The principal toxicity of 6MP is myelosuppression. Thrombocytopenia, granulocytopenia, or anemia may not become apparent for several weeks. Dose reduction usually results in prompt recovery, although myelosuppression may be severe and prolonged in patients with a polymorphism affecting TPMT. Anorexia, nausea, or vomiting is seen in about 25% of adults, but stomatitis and diarrhea are rare; manifestations of GI effects are less frequent in children than in adults. Jaundice and hepatic enzyme elevations occur in up to one-third of adult patients treated with 6MP and usually resolve on discontinuation of therapy. 6MP and its derivative azathioprine predispose to opportunistic infection (e.g., reactivation of hepatitis B, fungal infection, and Pneumocystis pneumonia) and an increased incidence of squamous cell malignancies of the skin. 6MP is teratogenic during the first trimester of pregnancy, and AML has been reported after prolonged 6MP therapy for Crohn disease.

Fludarabine Phosphate
Fludarabine phosphate is a fluorinated, deamination-resistant, phosphorylated analogue of the antiviral agent vidarabine (9-β-D-arabinofuranosyl-adenine). It is active in CLL and low-grade lymphomas and is also effective as a potent immunosuppressant.

Mechanisms of Action and Resistance
The drug is dephosphorylated extracellularly to the nucleoside fludarabine, which enters the cell and is phosphorylated by dCK to the active triphosphate. This antimitabolite inhibits DNA polymerase, DNA primase, DNA ligase, and RNR and becomes incorporated into DNA and RNA. The nucleotide is an effective chain terminator when incorporated into DNA (Kamiya et al., 1996). Incorporation of fludarabine into RNA inhibits RNA function, RNA processing, and mRNA translation.

Adverse Effects
Oral and intravenous therapy cause myelosuppression in about 50% of patients, nausea and vomiting in a minor fraction, and, uncommonly, chills and fever, malaise, anorexia, peripheral neuropathy, and weakness. Lymphopenia and thrombocytopenia and cumulative side effects are expected. Depletion of CD4+ T cells with therapy predisposes to opportunistic infections. Tumor lysis syndrome, a rare complication, occurs primarily in previously untreated patients with CLL. Altered mental status, seizures, optic neuritis, and coma have been observed at higher doses and in older patients. Autoimmune events may occur after fludarabine treatment. Patients with CLL may develop an acute hemolytic anemia or pure red cell aplasia during or following fludarabine treatment. Prolonged cytopenias, probably mediated by autoimmunity, also complicate fludarabine treatment. Myelodysplasia and acute leukemias may arise as late complications. Pneumonitis is an occasional side effect and responds to corticosteroids. In patients with compromised renal function, the initial doses should be reduced in proportion to the reduction in CrCl.

Cladribine
Cladribine is an ADA-resistant purine analogue that has potent and curative activity in hairy cell leukemia, CLL, and low-grade lymphomas.

Mechanisms of Action and Resistance
Cladribine enters cells via active nucleoside transport. After phosphorylation by dCK and conversion to cladribine triphosphate, it is incorporated into DNA. It produces DNA strand breaks and depletion of NAD and ATP, leading to apoptosis. It is a potent inhibitor of RNR. The drug does not require cell division to be cytotoxic. Resistance is associated with loss of the activating enzyme dCK; increased expression of RNR; or increased active efflux by ABCG2 or other members of the ABC family of transporters.

ADME
Cladribine is absorbed orally (55%) but is routinely administered intravenously. It is excreted by the kidneys, with a terminal t1/2 in plasma of 6.7 h. Cladribine crosses the blood-brain barrier and reaches CSF concentrations of about 25% of those seen in plasma. Doses should be adjusted for renal dysfunction.

Therapeutic Uses
Cladribine is administered daily for 7 days by continuous intravenous infusion. It is the drug of choice in hairy cell leukemia. Eighty percent of patients achieve a complete response after a single course of therapy. The drug also is active in CLL; low-grade lymphomas; Langerhans cell histiocytosis; CTCLs, including mycosis fungoides and the Sézary syndrome; and Waldenström macroglobulinemia.

Adverse Effects
The major dose-limiting toxicity of cladribine is myelosuppression. Cumulative thrombocytopenia may occur with repeated courses. Opportunistic infections are common and correlate with decreased CD4+ cell counts. Other toxic effects include nausea, infections, high fever, headache, fatigue, skin rashes, and tumor lysis syndrome.

Clofarabine (2-Chloro-2′-fluoroarabinosyladenine)
The analogue clofarabine (2-chloro-2′-fluoroarabinosyladenine) incorporates the 2-chloro, glycosylase-resistant substituent of cladribine and a 2′-fluoro-arabinosyl substitution, which adds stability and enhances uptake and phosphorylation. The resulting compound is approved for the treatment of pediatric AML after failure of two prior therapies. Clofarabine produces complete remissions in 20%–30% of these patients.
It has activity in pediatric and adult AML and in myelodysplasia. The uptake and metabolic activation of clofarabine in tumor cells follow the same path as cladribine and the other purine nucleosides, although clofarabine is more readily phosphorylated by dCK. Clofarabine triphosphate has a long intracellular $t_{\frac{1}{2}}$ (24 h). It incorporates into DNA, where it terminates DNA synthesis and leads to apoptosis; clofarabine also inhibits RNR.

**Therapeutic Uses and Adverse Effects**

In children, clofarabine is administered as a 2-h infusion daily for 5 days. The primary elimination $t_{\frac{1}{2}}$ in plasma is 6.5 h. Most of the drug is excreted unchanged in the urine. Doses should be adjusted according to reductions in ClCr. The primary toxicities are myelosuppression; a clinical syndrome of hypotension, tachyphemia, pulmonary edema, organ dysfunction, and fever, all suggestive of capillary leak syndrome and cytokine release that necessitate immediate discontinuation of the drug; elevated hepatic enzymes and increased bilirubin; nausea, vomiting, and diarrhea; and hypokalemia and hypophosphatemia.

**Nelarabine (6-Methoxy-arabinosyl-guanine)**

Nelarabine (6-methoxy-arabinosyl-guanine) is the only guanine nucleoside in clinical use. It has selective activity against acute T-cell leukemia (20% complete responses) and the closely related T-cell lymphoblastic lymphoma and is approved for use in patients with relapsed/refractory disease. Its basic mechanism of action closely resembles that of the other purine nucleosides, in that it is incorporated into DNA and terminates DNA synthesis.

**ADME**

Following infusion, the parent methoxy compound is rapidly activated in blood and tissues by ADA–mediated cleavage of the methyl group, yielding the phosphorylase-resistant Ara-G, which has a plasma $t_{\frac{1}{2}}$ of 3 h. The active metabolite is transported into tumor cells, where it is activated by dCK to Ara-GTP, which incorporates into DNA and terminates DNA synthesis. The drug and its metabolite Ara-G are primarily eliminated by metabolism to guanine, and a smaller fraction is eliminated by renal excretion of Ara-G. The drug should be used with close clinical monitoring in patients with severe renal impairment ($\text{ClCr} < 50 \text{mg/mL}$). Adults are given a 2-h infusion on days 1, 3, and 5 of a 21-day cycle, and children are given a lower dose for 5 days, repeated every 21 days.

**Adverse Effects**

The adverse effects include myelosuppression and liver function test abnormalities, as well as infrequent serious neurological sequelae, such as seizures, delirium, somnolence, peripheral neuropathy, or Guillain-Barré syndrome. Neurological adverse effects may not be reversible.

**Pentostatin (2′-Deoxycoformycin)**

Pentostatin (2′-deoxycoformycin; see Figure 66–9), a transition-state analogue of the intermediate in the ADA reaction, potently inhibits ADA. Its effects mimic the phenotype of genetic ADA deficiency (severe immunodeficiency affecting T-cell and B-cell functions).

**Mechanism of Action**

Inhibition of ADA by pentostatin leads to accumulation of intracellular adenosine and deoxyadenosine nucleotides, which can block DNA synthesis by inhibiting RNR. Deoxyadenosine also inactivates S-adenosyl homocysteine hydrolase. The resulting accumulation of S-adenosyl homocysteine is particularly toxic to lymphocytes. Pentostatin also inhibits RNA synthesis, and its triphosphate derivative is incorporated into DNA, resulting in strand breakage. Although the precise mechanism of cytotoxicity is not known, it is probable that the imbalance in purine nucleotide pools accounts for its antineoplastic effect in hairy cell leukemia and T-cell lymphomas.

**ADME**

Pentostatin is administered intravenously every other week and has a mean terminal $t_{\frac{1}{2}}$ of 5.7 h. After hydration with 500–1000 mL of 5% dextrose in half-normal (0.45%) saline, the drug is administered by rapid intravenous injection or by infusion over a period of 30 min or less, followed by an additional 500 mL of fluids. The drug is eliminated almost entirely by renal excretion. Proportional reduction of dosage is recommended in patients with renal impairment as measured by reduced ClCr.

**Therapeutic Use**

Pentostatin is effective in producing complete remissions (58%) and partial responses (28%) in patients with hairy cell leukemia. It largely has been superseded by cladribine (see previous discussion). Toxic manifestations include myelosuppression, GI symptoms, skin rashes, and abnormal liver function studies. Depletion of normal T cells occurs, and neutropenic fever and opportunistic infections may result. Immunosuppression may persist for several years after discontinuation. At high doses, major renal and neurological complications are encountered. Pentostatin in combination with fludarabine phosphate may result in severe or even fatal pulmonary toxicity.

### III. Natural Products

**Microtubule-Damaging Agents**

**Vinca Alkaloids**

Purified alkaloids from the periwinkle plant, including vinblastine and vincristine, were amongst the earliest clinical agents for the treatment of patients with leukemias, lymphomas, and testicular cancer. A closely related derivative, vinorelbine, has activity against lung and breast cancer.
observed in resistant cells in culture. Other membrane transporters, such as the MRP and the closely related BCRP, may contribute to resistance. Other forms of resistance to vinca alkaloids stem from mutations in β-tubulin or in the relative expression of isoforms of β-tubulin that prevent the inhibitors from effectively binding to their target.

**Adverse Effects**
The limited myelosuppressive activity of vincristine makes it a valuable component of several combination therapy regimens for leukemia and lymphoma, while the lack of severe neurotoxicity of vinblastine is a decided advantage in lymphomas and in combination with cisplatin against testicular cancer. Vinorelbine, which causes mild neurotoxicity and myelosuppression, has an intermediate toxicity profile.

**ADME**
Hepatic CYPs extensively metabolize all three drugs, and the metabolites are excreted in the bile. Only a small fraction of a dose (<15%) is found unchanged in the urine. In patients with hepatic dysfunction (bilirubin > 3 mg/dL), a 50%–75% reduction in dose of any of the vinca alkaloids is advisable. The elimination t1/2 is 20 h for vincristine, 23 h for vinblastine, and 24 h for vinorelbine.

**Vinblastine**
**Therapeutic Uses.** Vinblastine sulfate is given intravenously; special precautions must be taken against subcutaneous extravasation, which may cause painful irritation and ulceration. The drug should not be injected into an extremity with impaired circulation. After a single dose, myelosuppression reaches its maximum in 7–10 days. If a moderate level of leukopenia (3000 cells/mm³) is not attained, the weekly dose may be increased gradually. For testicular cancer, vinblastine is administered every 3 weeks. Doses should be reduced by 50% for patients with plasma bilirubin > 1.5 mg/dL. Vinblastine is used with bleomycin and cisplatin in the curative therapy of patients with metastatic testicular cancer, although it has been mainly supplanted by etoposide (see further discussion) or ifosfamide (see previous material). It is a component of the standard curative ABVD regimen for Hodgkin lymphoma. Vinblastine also is active against Kaposi sarcoma, neuroblastoma, Langerhans cell histiocytosis, bladder cancer, carcinoma of the breast, and choriocarcinoma.

**Adverse Effects.** Maximal leukopenia occurs within 7–10 days, after which recovery ensues within 7 days. Other toxic effects of vinblastine include mild neurological manifestations. GI disturbances, including nausea, vomiting, anorexia, and diarrhea, may be encountered. The syndrome of inappropriate secretion of antidiuretic hormone has been reported. Loss of hair, stomatitis, and dermatitis occur infrequently. Extravasation during injection may lead to cellulitis and phebitis.

**Vincristine**
**Therapeutic Uses.** Vincristine is a standard component of regimens for treating pediatric patients with leukemias, lymphomas, and solid tumors, such as Wilms tumor, neuroblastoma, and rhabdomyosarcoma. In large-cell non-Hodgkin lymphomas, vincristine remains an important agent, particularly when used in the CHOP regimen. Vincristine with glucocorticoids is the treatment of choice to induce remissions in patients with childhood leukemia and in combination with alkylating agents and anthracycline for those with pediatric sarcomas. The common intravenous dosage for vincristine is 2 mg/m² of body surface area per week or longer intervals. Vincristine is tolerated better by children than by adults, who may experience severe, progressive neurological toxicity and require lowering of the dose. Administration of the drug more frequently than every 7 days or at higher doses increases the toxic manifestations without proportional improvement in the response rate. Precautions also should be used to avoid extravasation during intravenous administration. Doses should be reduced for patients with elevated plasma bilirubin.

**Adverse Effects.** The clinical toxicity of vincristine is mostly neurological. Severe neurological manifestations may be reversed by suspending therapy or reducing the dosage at the first sign of motor dysfunction. Severe constipation, sometimes resulting in colicky abdominal pain and obstruction, may be prevented by laxatives and hydrophilic (bulk-forming) agents and usually is a problem only with doses greater than 2 mg/m². Reversible alopecia occurs in about 20% of patients. Modest leukopenia may occur. Thrombocytopenia, anemia, and the syndrome of inappropriate secretion of antidiuretic hormone are less common. Inadvertent injection of vincristine into the CSF causes a devastating and often-fatal irreversible coma and seizures.

**Vinorelbine**
Vinorelbine has activity against non–small cell lung cancer and breast cancer. Vinorelbine is administered in normal saline as an intravenous infusion over 6–10 min. When used alone, it is given at doses of 30 mg/m² either weekly or for 2 of every 3 weeks. When used with cisplatin for the treatment of non–small cell lung cancer, it is given at doses of 25 mg/m² either weekly or for 3 of every 4 weeks. A lower dose (20–25 mg/m²) may be required for patients who have received prior chemotherapy and for hematological toxicity. The primary adverse effect of vinorelbine is granulocytopenia, with only modest thrombocytopenia and less neurotoxicity than other vinca alkaloids. Vinorelbine may cause allergic reactions and mild, reversible changes in liver enzymes. Doses should be reduced in patients with elevated plasma bilirubin.

**Eribulin**
Eribulin is a synthetic analogue of halichondrin, a poly-ether macrolide, originally isolated from the Pacific marine sponge Halichondria okadai. The drug binds to the vinca alkaloid site on β-tubulin and inhibits microtubule assembly. Eribulin is a poorer substrate than other microtubule disruptors for the Pgp efflux pump and is effective in drug-resistant tumors that overexpress Pgp. Eribulin is approved for the treatment of patients with drug-resistant metastatic breast cancer and liposarcoma. Adverse effects overlap with those of the vinca alkaloids and include neutropenia, neuropathies, and GI toxicities.

**Taxanes**
Paclitaxel was first isolated from the bark of the Western yew tree. Paclitaxel and its semisynthetic congeners docetaxel and cabazitaxel, exhibit unique pharmacological properties as inhibitors of mitosis. These taxanes differ from the vinca alkaloids and colchicine derivatives in that they bind to a different site on β-tubulin and promote rather than inhibit microtubule formation (Figure 66–10), stabilizing tubulin-GDP (Akhnmana and Steinmetz, 2015). The taxanes have a central role in the therapy of patients with ovarian, breast, lung, GI, genitourinary, prostate, and head and neck cancers.
Mechanism of Action
Paclitaxel binds to the β-tubulin subunit on the inner surface of microtubules and antagonizes their disassembly (Figure 66–10), with the result that bundles of microtubules and aberrant structures derived from microtubules appear in the mitotic phase of the cell cycle. Arrest in mitosis follows. Cell death occurs by apoptosis and depends on both drug concentration and duration of drug exposure. Drugs that block cell-cycle progression prior to mitosis antagonize the toxic effects of taxanes.

Drug interactions have been noted. The sequence of cisplatin preceding paclitaxel decreases paclitaxel clearance and produces greater toxicity than the opposite schedule. Paclitaxel decreases doxorubicin clearance and enhances its cardiotoxicity; docetaxel has no apparent effect on anthracycline pharmacokinetics.

Resistance to taxanes can be a result of decreased cellular drug accumulation due to increased expression of membrane-bound efflux proteins, including MRPI and Pgp. Cabazitaxel is a poor substrate for Pgp and may therefore be useful for treating multidrug-resistant tumors. Other mechanisms of resistance may include an increase in survivin, an antiapoptotic factor; an increase in a-aurora kinase, which promotes completion of mitosis; an upregulation of the βIIH-isofrom of tubulin that lacks taxane-binding capacity; or a direct alteration of the drug target by mutation.

ADME
Paclitaxel has limited water solubility and is administered in a vehicle of 50% ethanol and 50% polyethylene glycol 400. Hepatic CYPs (primarily CYP2C8, secondarily CYP3A4) extensively metabolize the drug. The primary metabolite is 6-OH paclitaxel, which is inactive; multiple additional hydroxylation products are found in plasma; less than 10% of a dose is excreted in the urine intact. Dose reductions in patients with abnormal hepatic function have been suggested, and 50–75% of doses of taxanes should be used in the presence of hepatic metastases larger than 2 cm in size or in patients with abnormal serum bilirubin. Drugs that induce CYP2C8 or CYP3A4, such as phenytoin and phenobarbital, or those that inhibit these CYPs, such as antifungal imidazoles, significantly alter drug clearance and toxicity.

Paclitaxel clearance is nonlinear and decreases with increasing dose or dose rate; the plasma t½ is 10–14 h. The critical plasma concentration for myelosuppression depends on the duration of exposure but likely is 50–100 nM. Paclitaxel clearance is markedly delayed by cyclosporine A and other drugs that inhibit Pgp.

An albumin-bound nanoparticle solution for infusion (nab-paclitaxel) is soluble in aqueous solutions. This form of paclitaxel has increased cellular uptake via an albumin-specific mechanism. Nab-paclitaxel achieves a higher serum concentration than paclitaxel, but the increased clearance of nab-paclitaxel results in a similar systemic drug exposure. It is somewhat less neurotoxic than paclitaxel and is approved for metastatic non–small cell lung cancer. Like the other taxanes, nab-paclitaxel should not be given to patients with an absolute neutrophil count below 1500 cells/mm³.

Docetaxel, somewhat more soluble than paclitaxel, is administered intravenously in an emulsifier (polysorbate 80). Docetaxel pharmacokinetics are similar to those of paclitaxel, with an elimination t½ of about 12 h. Clearance is primarily through CYP3A4- and CYP3A5-mediated hydroxylation, leading to inactive metabolites.

Therapeutic Uses
The taxanes have become central components of regimens for treating patients with metastatic ovarian, breast, lung, GI, genitourinary, and head and neck cancers. These drugs are administered once weekly or once every 3 weeks. Cabazitaxel is a poor substrate for Pgp and is approved for hormone-refractory metastatic prostate cancer previously treated with a docetaxel-containing regimen.

Adverse Effects
Paclitaxel exerts its primary toxic effects on the bone marrow. Neutropenia usually occurs 8–11 days after a dose and reverses rapidly by days 15–21. Used with G-CSF, high doses over 24 h are well tolerated, and peripheral neuropathy becomes dose limiting. Many patients experience myalgias after receiving paclitaxel. In high-dose schedules, or with prolonged use, a stocking-glove sensory neuropathy can be disabling, particularly in patients with underlying diabetic neuropathy or concurrent cisplatin therapy. Mucositis is prominent in 72- or 96-h infusions and in the weekly schedule. Hypersensitivity reactions can occur in patients receiving paclitaxel infusions of short duration (1–6 h) but are largely averted by pretreatment with dexamethasone, diphenhydramine, and histamine H₂ receptor antagonists. Premedication is not necessary with 96-h infusions. Many patients experience symptomatic bradycardia; occasional episodes of silent ventricular tachycardia also occur and resolve spontaneously during 3- or 24-h infusions. Nab-paclitaxel produces increased rates of peripheral neuropathy compared to the original cremophor-delivered paclitaxel but rarely causes hypersensitivity reactions.

Docetaxel causes greater degrees of neutropenia than paclitaxel but less peripheral neuropathy and asthenia and less frequent hypersensitivity. Fluid retention is a persistent problem with multiple cycles of docetaxel therapy, leading to peripheral edema, pleural and peritoneal fluid, and pulmonary edema in extreme cases. Oral dexamethasone, begun 1 day prior to drug infusion and continuing for 3 days, greatly ameliorates fluid retention. In rare cases, docetaxel may cause progressive interstitial pneumonitis and respiratory failure if the drug is not discontinued.

Estramustine
Estramustine combines estradiol and normustine (nitrogen mustard) through a carbamate link. Although the intent of the combination was to enhance the uptake of the alkylating agent into estradiol-sensitive prostate cancer cells, estramustine does not function in vivo as an alkylating agent; rather, it binds to β-tubulin and microtubule-associated proteins, causing microtubule disassembly and antimitotic actions.

Therapeutic Use
Estramustine is used solely for the treatment of patients with metastatic or locally advanced hormone-refractory prostate cancer.

ADME
Following oral administration, at least 75% of a dose of estramustine phosphate is absorbed from the GI tract and rapidly dephosphorylated. The drug undergoes extensive first-pass metabolism by hepatic CYPs to an active 17-keto derivative, estromustine, and to multiple inactive products; the active drug forms accumulate in the prostate. Some hydrolysis of the carbamate linkage occurs in the liver, releasing estradiol, estrone, and the normustine group. Estramustine and estromustine have plasma half-lives of 10 and 14 h, respectively, and are excreted as inactive metabolites, mainly in the feces.

Adverse Effects, Drug Interactions
In addition to myelosuppression, estramustine also possesses estrogenic side effects (gynecomastia, impotence, elevated risk of thrombosis, and fluid retention); hypercalcemia; acute attacks of porphyria; impaired glucose tolerance; and hypersensitivity reactions, including angioedema. Estramustine inhibits the clearance of taxanes.

Epothilones
The epothilones are polyketides discovered as cytotoxic metabolites from a strain of Sorangium cellulosum, a myxobacterium isolated from soil on the bank of the Zambezi River in southern Africa (Gerth et al., 1996). One of these, ixabepilone, is approved for breast cancer treatment; others are under development (Lee and Swain, 2008).
Ixabepilone

Mechanism of Action; Resistance. Epothilones bind to a β-tubulin site distinct from that of taxanes and trigger microtubule nucleation at multiple sites away from the centrosome. This dysfunctional microtubule stabilization triggers cell-cycle arrest at the G_{2}-M interface and apoptosis. In vitro studies suggested that ixabepilone is less susceptible to Pgp-mediated export and multidrug resistance than taxanes. Mechanisms implicated in epothilone resistance include mutation of the β-tubulin binding site and export and multidrug resistance than taxanes. Mechanisms implicated in epothilone resistance include mutation of the β-tubulin binding site and upregulation of isoforms of β-tubulin.

ADME. Ixabepilone is administered intravenously. Because of its minimal aqueous solubility, it is delivered in the solubilizing agent cremophor (polyoxyethylated castor oil/ethanol), which has been implicated as the cause of infusion reactions; such reactions are infrequent when administration is preceded by premedication with H1 and H2 antagonists. The drug is cleared by hepatic CYPs and has a plasma t\textsubscript{1/2} of 52 h.

Therapeutic Uses. In patients with metastatic breast cancer resistant to or pretreated with anthracyclines and resistant to taxanes, ixabepilone plus capecitabine provides an improved progression-free survival of 1.6 months compared to capecitabine alone. Ixabepilone also is indicated as monotherapy for metastatic breast cancer in patients who have previously progressed through treatment with anthracyclines, taxanes, and capecitabine. Ixabepilone (~40 mg/m]\textsuperscript{2}) is administered as monotherapy or in combination with capecitabine over 3 h every 3 weeks. Patients should be premedicated with both an H\textsubscript{1} and an H\textsubscript{2} antagonist before receiving ixabepilone to minimize hypersensitivity reactions. In patients with mild-to-moderate hepatic dysfunction who receive ixabepilone monotherapy, lower starting doses are recommended due to delayed drug clearance.

Adverse Effects. Epothilones have toxicities similar to those of the taxanes: neutropenia, peripheral sensory neuropathy, fatigue, diarrhea, and asthenia.

Camptothecin Analogues

The camptothecins are potent, cytotoxic antineoplastic agents that target the nuclear enzyme topoisomerase I. The lead compound in this class, camptothecin, was isolated from the tree Camptotheca acuminata. Irinotecan and topotecan, currently the only camptothecin analogues approved for clinical use, have activity in colorectal, ovarian, and small cell lung cancer.

Chemistry

All camptothecins have a fused five-ring backbone that includes a labile lactone ring (Figure 66–11). The hydroxyl group and S conformation of the chiral center at C20 in the lactone ring are required for biological activity. Appropriate substitutions on the A and B rings of the quinoline subunit enhance water solubility and increase potency for inhibiting topoisomerase I. Topotecan is a semisynthetic molecule with a basic dimethylamino group that increases its water solubility. Irinotecan (CPT-11) differs from topotecan in that it is a prodrug. The carbamate bond between the camptothecin moiety and the dibasic bis-piperidine side chain at position C10 (which makes the molecule water soluble) is cleaved by a carboxylesterase to form the active metabolite SN-38 (see Figure 6–6).

Mechanism of Action

The DNA topoisomerases are nuclear enzymes that reduce torsional stress in supercoiled DNA, allowing selected regions of DNA to become sufficiently untangled to permit replication, repair, and transcription. Two classes of topoisomerase (I and II) mediate DNA strand breakage and rescaling. Camptothecin analogues inhibit the function of topoisomerase I; other drugs, such as anthracyclines, epipodophyllotoxins, and acridines, inhibit topoisomerase II. The camptothecins bind to and stabilize the normally transient DNA–topoisomerase I cleavable complex. Although the initial cleavage action of topoisomerase I is not affected, the religation step is inhibited, leading to the accumulation of single-stranded breaks in DNA. These lesions are reversible and not by themselves toxic to the cell. However, the collision of a DNA replication fork with this cleaved strand of DNA causes an irreversible double-strand DNA break, ultimately leading to cell death.

Camptothecins are S phase-specific drugs because ongoing DNA synthesis is necessary for cytotoxicity. This has important clinical implications. S phase–specific cytotoxic agents generally require prolonged exposures of tumor cells to drug concentrations above a minimum threshold for optimal therapeutic efficacy. In fact, low-dose, protracted administration of camptothecin analogues has less toxicity, and equal or greater antitumor activity, than shorter, more intense courses.

Mechanisms of Resistance

Decreased intracellular drug accumulation may underlie resistance. Topotecan, but not irinotecan, is a substrate for Pgp; however, compared with other substrates, such as etoposide or doxorubicin, topotecan is a relatively poor substrate. Nonetheless, the BCRP/xenobiotic exporter ABCG2/BCRP is overexpressed in cultured cells that have become resistant to irinotecan after exposure to camptothecins. Cell lines that lack carboxylesterase activity demonstrate resistance to irinotecan, but the liver and red blood cells may have sufficient carboxylesterase activity to convert irinotecan to the active metabolite SN-38. Camptothecin resistance also may result from decreased expression or mutation of topoisomerase I. A transient downregulation of topoisomerase I has been demonstrated following prolonged exposure to camptothecins in vitro and in vivo. Mutations leading to reduced topoisomerase I enzyme catalytic activity or DNA-binding affinity have been associated with experimental camptothecin resistance. Finally, exposure of cells to topoisomerase I-targeted agents upregulates topoisomerase II, an alternative enzyme for DNA strand passage.

Topotecan

ADME

Topotecan is approved for intravenous administration. An oral dosage form in development has a bioavailability of 30%–40% in patients with cancer. Topotecan exhibits linear pharmacokinetics, and it is rapidly eliminated from systemic circulation with a t\textsubscript{1/2} of about 3.5–4.1 h. Only 20%–35% of the total drug in plasma is found to be in the active lactone form. Within 24 h, 30%–40% of the administered dose appears in the urine. Doses should be reduced in proportion to reductions in Cl\textsubscript{cr}. Hepatic metabolism appears to be a relatively minor route of drug elimination. Plasma protein binding of topotecan is low (7%–35%), which may explain its relatively greater CNS penetration.

Therapeutic Uses

Topotecan is indicated for previously treated patients with ovarian and small cell lung cancer. Significant hematological toxicity limits its use in combination with other active agents in these diseases (e.g., cisplatin). The recently extended dosing regimen of topotecan for ovarian cancer and small
cell lung cancer is a 30-min infusion for 5 consecutive days every 3 weeks. For the treatment of patients with cervical cancer in conjunction with cisplatin, topotecan is administered on days 1, 2, and 3, repeated every 21 days. The dose of topotecan should be reduced in patients with moderate renal dysfunction (CLCr of 20–40 mL/min); topotecan should not be administered to patients with severe renal impairment (CLCr < 20 mL/min). Hepatic dysfunction does not alter topotecan clearance and toxicity. A baseline neutrophil count greater than 1500 cells/mm³ and a platelet count above 100,000 is necessary prior to topotecan administration.

**Adverse Effects**

The dose-limiting toxicity with all dosing schedules is neutropenia, with or without thrombocytopenia. The incidence of severe neutropenia at 1.5 mg/m² daily for 5 days every 3 weeks may be as high as 81%, with a 26% incidence of febrile neutropenia. In patients with hematological malignancies, GI side effects such as mucositis and diarrhea become dose limiting. Other less common and generally mild topotecan-related toxicities include nausea and vomiting, elevated liver transaminases, fever, fatigue, and rash.

**Irinotecan**

**ADME**

The conversion of irinotecan to its active metabolite SN-38 is mediated predominantly by carboxylesterases in the liver (see Figures 6–6 and 6–7). Although SN-38 can be measured in plasma shortly after beginning an intravenous infusion of irinotecan, the AUC of SN-38 is only about 4% of the AUC of irinotecan, suggesting that only a relatively small fraction of the dose is ultimately converted to the active form of the drug. Irinotecan exhibits linear pharmacokinetics. In comparison to topotecan, a relatively large fraction of both irinotecan and SN-38 are present in plasma as the biologically active intact lactone form. The t¹/₂ of SN-38 is 11.5 h, three times that of topotecan. CSF penetration of SN-38 in humans has not been characterized.

In contrast to topotecan, hepatic metabolism of irinotecan and SN-38 represents an important route of elimination for both. Oxidative metabolites have been identified in plasma, all of which result from CYP3A-mediated reactions directed at the bispiperidine side chain. These metabolites are not significantly converted to SN-38. The total body clearance of irinotecan was found to be two times greater in patients with brain cancer taking antiseizure drugs that induce hepatic CYPs.

UGT1A1 glucuronidates the hydroxy group at position C10 (resulting from cleavage of the bispiperidine promoiety), producing the inactive glucuronide metabolite SN-38G (see Figures 6–6 and 6–7). Biliary excretion appears to be the primary elimination route of irinotecan, SN-38, and metabolites, although urinary excretion also contributes (14%–37%). The extent of SN-38 glucuronidation inversely correlates with the risk of severe diarrhea after irinotecan therapy. UGT1A1 polymorphisms associated with familial hyperbilirubinemia syndromes may have a major impact on the clinical use of irinotecan. In patients treated with irinotecan, there is a positive correlation between baseline serum unconjugated bilirubin concentration and both severity of neutropenia and the AUC of irinotecan and SN-38. Severe irinotecan toxicity has been observed in patients with cancer with Gilbert syndrome, presumably due to decreased glucuronidation of SN-38. In patients with the syndrome, elevated levels of unconjugated bilirubin in the bloodstream are due to reduced activity of glucuronosyl transferase. The presence of bacterial glucuronidase in the intestinal lumen potentially can contribute to irinotecan GI toxicity by releasing unconjugated SN-38 from the inactive glucuronide metabolite.

**Therapeutic Uses**

Single-agent dosage of irinotecan is by weekly infusion for 4 of 6 weeks, with a higher dose given every 3 weeks. In patients with advanced colorectal cancer, irinotecan is used as first-line therapy in combination with fluoropyrimidines or as a single agent or in combination with cetuximab following failure of a 5FU/oxaliplatin regimen. It also has activity in small cell lung cancer. A irinotecan liposome injection in combination with 5FU and leucovorin was recently approved by the FDA for treatment of metastatic pancreatic cancer after disease progression following gemcitabine therapy.

**Adverse Effects**

The dose-limiting toxicity with all dosing schedules is delayed diarrhea (35%), with or without neutropenia. An intensive regimen of loperamide (see Chapter 49) reduces this incidence by more than half. However, once severe diarrhea occurs, standard doses of anti-diarrheal agents tend to be ineffective. Diarrhea generally resolves within a week and, unless associated with fever and neutropenia, rarely is fatal.

The second most common irinotecan-associated toxicity is myelosuppression. Severe neutropenia occurs in 14%–47% of the patients treated with a schedule of administration every 3 weeks and is less frequently encountered amongst patients treated with the weekly schedule. Febrile neutropenia is observed in 3% of patients and may be fatal, particularly when associated with concomitant diarrhea. A cholinergergic syndrome resulting from the inhibition of acetylcholinesterase activity by irinotecan may occur within the first 24 h after irinotecan administration. Symptoms include acute diarrhea, diaphoresis, hypersalivation, abdominal cramps, visual accommodation disturbances, lacrimation, rhinorrhea, and, less often, asymptomatic bradycardia. These effects are short lasting and respond within minutes to atropine. Other common toxicities include nausea and vomiting, fatigue, vasodilation or skin flushing, mucositis, elevation in liver transaminases, and alopecia. There have been case reports of dyspnea and interstitial pneumonitis associated with irinotecan therapy.

**Antibiotics**

**Dactinomycin (Actinomycin D)**

Actinomycins are chromopeptides isolated from Streptomyces soil bacteria. Most contain the same chromophore, the planar phenoxazone actinosin, which is responsible for their yellow-red color. The differences amongst naturally occurring actinomycins are confined to variations in the structure of the amino acids of the peptide side chains. Actinomycin D has beneficial effects in the treatment of solid tumors in children and choriocarcinoma in adult women.

**Mechanism of Action**

The capacity of actinomycins to bind to double-helical DNA is responsible for their biological activity and cytotoxicity. The planar phenoxazone ring intercalates between adjacent guanine–cytosine base pairs of DNA, while the polypeptide chains extend along the minor groove of the helix, resulting in a dactinomycin-DNA complex with stability sufficient to block the transcription of DNA by RNA polymerase. The DNA-dependent RNA polymerases are much more sensitive to the effects of dactinomycin than are the DNA polymerases. In addition, dactinomycin causes single-strand breaks in DNA, possibly through a free-radical intermediate or as a result of the action of topoisomerase II. Dactinomycin inhibits rapidly proliferating cells of normal and neoplastic origin and is amongst the most potent antitumor agents known.

**ADME**

Dactinomycin is administered by intravenous injection. Metabolism of the drug is minimal. The drug is excreted in both bile and urine and disappears from plasma with a terminal t¹/₂ of 36 h. Dactinomycin does not cross the blood-brain barrier.

**Therapeutic Uses**

Dactinomycin is given intravenously for 5 days, usually in the range of 10–15 μg/kg. If no manifestations of toxicity are encountered, additional courses may be given at intervals of 2–4 weeks, although weekly maintenance doses have been used. The main clinical use of dactinomycin is in the treatment of rhabdomyosarcoma and Wilms tumor in children, where it is curative in combination with primary surgery, radiotherapy, and other drugs, particularly vincristine and cyclophosphamide. Ewing, Kaposi, and soft-tissue sarcomas also respond. Dactinomycin and MTX form a curative therapy for choriocarcinoma.
Mechanisms of Action and Resistance

Anthracyclines are derived from the fungus Streptomyces peucetius var. caesius. Idarubicin and epirubicin are analogues of the naturally produced anthracyclines doxorubicin and daunorubicin, differing only slightly in chemical structure, but having somewhat distinct patterns of clinical activity. Daunorubicin and idarubicin primarily have been used in acute leukemias, whereas doxorubicin and epirubicin display broader activity against solid tumors. These agents, which possess the potential for generating free radicals, cause an unusual and often-irreversible cardiomyopathy, the occurrence of which is related to the total dose of the drug. The structurally similar agent mitoxantrone has less cardiotoxicity and is useful against prostate cancer and AML and in high-dose chemotherapy.

Adverse Effects

Toxic manifestations include anorexia, nausea, and vomiting, usually beginning a few hours after administration. Hematopoietic suppression with pancytopenia may occur in the first week after completion of therapy. Proctitis, diarrhea, glossitis, cheilitis, and ulcerations of the oral mucosa are common; dermatological manifestations include alopecia, as well as erythema, desquamation, and increased inflammation and pigmentation in areas previously or concomitantly subjected to X-ray radiation. Severe injury may occur as a result of local drug extravasation; the drug is extremely corrosive to soft tissues.

Anthracyclines and Anthracenediones

Anthracyclines are derived from the fungus Streptomyces peucetius var. caesius. Idarubicin and epirubicin are analogues of the naturally produced anthracyclines doxorubicin and daunorubicin, differing only slightly in chemical structure, but having somewhat distinct patterns of clinical activity. Daunorubicin and idarubicin primarily have been used in acute leukemias, whereas doxorubicin and epirubicin display broader activity against solid tumors. These agents, which possess the potential for generating free radicals, cause an unusual and often-irreversible cardiomyopathy, the occurrence of which is related to the total dose of the drug. The structurally similar agent mitoxantrone has less cardiotoxicity and is useful against prostate cancer and AML and in high-dose chemotherapy.

Mechanisms of Action and Resistance

Anthracyclines and anthracenediones can intercalate with DNA, directly affecting transcription and replication. More important is their capacity to form a heterotrimeric complex with topoisomerase II and DNA. Topoisomerase II produces double-strand breaks at the 3'-phosphate backbone, allowing strand passage and uncoiling of supercoiled DNA. Following strand passage, topoisomerase II religates the DNA strands; this enzyme function is essential for DNA replication and repair. Formation of the ternary complex with anthracyclines or with etoposide inhibits the religation of the broken DNA strands, leading to apoptosis. Defects in DNA double-strand break repair sensitize cells to damage by these drugs, while altered DNA damage-sensing and DNA repair capacity may contribute to resistance.

The quinone moieties of anthracyclines can form radical intermediates that react with O₂ to produce superoxide anion radicals, which can produce •OH that attack DNA and oxidize DNA bases, leading to apoptosis (Serrano et al., 1999). The production of free radicals is significantly stimulated by the interaction of doxorubicin with iron. Enzymatic defenses such as superoxide dismutase and catalase protect cells against the toxicity of the anthracyclines, and these defenses can be augmented by exogenous antioxidants such as α-tocopherol or by the iron chelator deferoxoxane, which protects against cardiac toxicity. Multidrug resistance is observed in tumor cell populations exposed to anthracyclines. Anthracyclines also are exported from tumor cells by members of the MRP transporter family and by ABCG2 (BCRP). Other biochemical changes in resistant cells include increased glutathione peroxidase activity, decreased activity or mutation of topoisomerase II, and enhanced ability to repair DNA strand breaks.

ADME

Daunorubicin, doxorubicin, epirubicin, and idarubicin are administered intravenously and are cleared by a complex pattern of hepatic metabolism and biliary excretion. Each anthracycline is converted to an active alcohol intermediate that plays a variable role in the therapeutic activity. The plasma disappearance curves for doxorubicin and daunorubicin are multiphasic, with a terminal t₁/₂ of 30 h. Idarubicin has a t₁/₂ of 15 h, and its active metabolite, idarubicinol, has a t₁/₂ of 40 h. The drugs rapidly enter the heart, kidneys, lungs, liver, and spleen; they do not cross the blood-brain barrier. Clearance is delayed in the presence of hepatic dysfunction; at least a 50% initial reduction in dose should be considered in patients with elevated serum bilirubin levels.

Idarubicin and Daunorubicin

Therapeutic Use. Idarubicin (~12 mg/m²/d for 3 days) is administered by slow intravenous injection (10–15 min) to avoid extravasation. Treatment is for 3 days. Idarubicin has less cardiotoxicity than the other anthracyclines. Daunorubicin (also named daunomycin or rubidomycin) is administered (at 24–45mg/m²/d) intravenously for 3 days, with care to prevent extravasation. Total doses greater than 1000 mg/m² are associated with a high risk of cardiotoxicity. Daunorubicin may impart a red color to the urine. Daunorubicin and idarubicin are used in the treatment of patients with AML in combination with Ara-C.

Adverse Effects. Toxic effects of daunorubicin and idarubicin include bone marrow depression, stomatitis, alopecia, GI disturbances, rash, and cardiac toxicity. Cardiac toxicity of anthracyclines can be acute or chronic and is described in detail next for doxorubicin.

Doxorubicin

Therapeutic Use. The dose (60–75 mg/m²) is administered as a single rapid intravenous infusion that is repeated after 21 days. A doxorubicin liposomal product is available for treatment of AIDS-related Kaposi sarcoma and is given intravenously in a dose of 20 mg/m² over 60 min and repeated every 3 weeks. The liposomal formulation also is approved for ovarian cancer for treatment at a dose of 50 mg/m² every 4 weeks and as a treatment of multiple myeloma (in conjunction with bortezomib), where it is given as a 30–mg/m² dose on day 4 of each 21-day cycle. Patients should be advised that the drug may impart a red color to the urine. Doxorubicin is effective in malignant lymphomas. In combination with cyclophosphamide, vinca alkaloids, and other agents, it is an important ingredient for the successful treatment of lymphomas. It is a valuable component of various regimens of chemotherapy for adjuvant and metastatic carcinoma of the breast. The drug also is beneficial in pediatric and adult sarcomas, including osteogenic, Ewing, and soft-tissue sarcomas.

Adverse Effects. Toxicities of doxorubicin are similar to those of daunorubicin. Myelosuppression is a major dose-limiting complication, with maximal leukopenia usually occurring during the second week of therapy and recovery by the fourth week; thrombocytopenia and anemia follow a similar pattern but usually are less pronounced. Stomatitis, mucositis, diarrhea, and alopecia are common but reversible. Erythematous streaking near the site of infusion (“flare”) is a benign local allergic reaction and should not be confused with extravasation. Facial flushing, conjunctivitis, and laceration may occur rarely. The drug may produce severe local toxicity in irradiated tissues (e.g., the skin, heart, lung, esophagus, and GI mucosa) even when the two therapies are not administered concomitantly.

Cardiomyopathy is the most important long-term toxicity (Rochette et al., 2015) and may take two forms:

• An acute form, characterized by abnormal electrocardiographic changes, including ST- and T-wave alterations and arrhythmias. This is brief and rarely a serious problem. An acute reversible reduction in ejection fraction is observed in some patients in the 24 h after a single dose, and plasma troponin T may increase in a minority of patients in
the first few days following drug administration (Lipshultz et al., 2004). Acute myocardial damage, the "pericarditis-myocarditis syndrome," may begin in the days following drug infusion and is characterized by severe disturbances in impulse conduction and frank congestive heart failure, often associated with pericardial effusion.

- Chronic, cumulative, dose-related toxicity (usually total doses of ≥ 550 mg/m$^2$) progressing to congestive heart failure. The mortality rate in patients with congestive failure approaches 50%. The risk of cardiomyopathy increases markedly with dose; estimates run as high as 20% at total doses of 550 mg/m$^2$ (a total dose limit of 300 mg/m$^2$ is advised for pediatric cases). These total dosages should be exceeded only under exceptional circumstances or with the concomitant use of dexrazoxane, a cardioprotective iron-chelating agent (Swain et al., 1997). Cardiac irradiation, administration of high doses of cyclophosphamide or another anthracycline, or concomitant trastuzumab increases the risk of cardiotoxicity (Slamon et al., 2001). Late-onset cardiac toxicity, with congestive heart failure years after treatment, may occur in both pediatric and adult populations. In children treated with anthracyclines, there is a 3- to 10-fold elevated risk of arrhythmias, congestive heart failure, and sudden death in adult life. Concomitant administration of dexrazoxane may reduce troponin T elevations and avert later cardiotoxicity (Lipshultz et al., 2004).

**Etoposide and Teniposide**

Mechanisms of Action and Resistance

Etoposide and teniposide form ternary complexes with topoisomerase II inhibitor that is approved for use in AML, prostate cancer, and late-stage, secondary progressive multiple sclerosis. Etoposide has limited ability to produce quinone-type free radicals and causes less cardiac toxicity than does doxorubicin. It produces acute myelosuppression, cardiac toxicity, and mucositis as its major toxicities; the drug also causes nausea, vomiting, and alopecia, although less than doxorubicin. Mitoxantrone is administered by intravenous infusion. To induce remission in acute non-lymphocytic leukemia in adults, the drug is given in a daily dose of 12 mg/m$^2$ for 3 days with cytarabine. It also is used in advanced hormone-resistant prostate cancer in a dose of 12–14 mg/m$^2$ every 21 days.

**Epipodophyllotoxins**

Podophyllotoxin Derivatives

Two synthetic derivatives of podophyllotoxins have significant therapeutic activity in pediatric leukemia, small cell carcinomas of the lung, testicular tumors, Hodgkin disease, and large cell lymphomas. These derivatives are etoposide (VP-16-213) and teniposide (VM-26). Although podophyllotoxin binds to tubulin, etoposide and teniposide have no effect on microtubular structure or function at usual concentrations.

**Mechanisms of Action and Resistance**

Etoposide and teniposide form ternary complexes with topoisomerase II and DNA and prevent resealing of the break that normally follows topoisomerase activity. The enzyme remains bound to the free end of the broken DNA strand, leading to an accumulation of DNA breaks and cell death. Cells in the S and G$\_2$ phases of the cell cycle are most sensitive to etoposide and teniposide. Resistant cells demonstrate (1) amplification of the $MDR1$ gene that encodes the Pgp drug efflux transporter, (2) mutation or decreased expression of topoisomerase II, or (3) mutations of the P53 tumor suppressor gene, a required component of the apoptotic pathway (Lowe et al., 1993).

**Etoposide**

**ADME**

Oral administration of etoposide results in variable absorption that averages about 50%. After intravenous injection, there is a biphasic pattern of clearance with a terminal $t_{1/2}$ of about 6–8 h in patients with normal renal function. Approximately 40% of an administered dose is excreted intact in the urine. In patients with compromised renal function, dosage should be reduced in proportion to the reduction in Cl$_{CR}$. In patients with advanced liver disease, increased toxicity may result from a low serum albumin (decreased drug binding) and elevated bilirubin (which displaces etoposide from albumin); guidelines for dose reduction in this circumstance have not been defined. Drug concentrations in the CSF average 1%–10% of those in plasma.

**Therapeutic Uses**

The intravenous dose of etoposide for testicular cancer in combination therapy (with bleomycin and cisplatin) is 50–100 mg/m$^2$ for 5 days or 100 mg/m$^2$ on alternate days for three doses. For small cell carcinoma of the lung, the dosage in combination therapy (with cisplatin) is 100–200 mg/m$^2$/d intravenously for 3 days. Cycles of therapy usually are repeated every 3–4 weeks. After relapse, oral administration of 50 mg/m$^2$/d for 21 days is one treatment option. When given intravenously, the drug should be administered slowly over a 30- to 60-min period to avoid hypotension and bronchospsam, which likely result from the additives used to dissolve etoposide.

Etoposide is also active against non-Hodgkin lymphomas, acute nonlymphocytic leukemia, and Kaposi sarcoma associated with AIDS. Etoposide has a favorable toxicity profile for dose escalation in that its primary acute toxicity is myelosuppression. In combination with ifosfamide and carboplatin, it frequently is used for high-dose chemotherapy in total doses of 1500–2000 mg/m$^2$.

**Adverse Effects**

The dose-limiting toxicity of etoposide is leukopenia (nadir at 10–14 days, recovery by 3 weeks). Thrombocytopenia occurs less often and usually is not severe. Nausea, vomiting, stomatitis, and diarrhea complicate treatment in about 15% of patients. Alopecia is common but reversible. Hepatic toxicity is particularly evident after high-dose treatment. For both etoposide and teniposide, toxicity increases in patients with decreased serum albumin, an effect related to decreased protein binding of the drug. A disturbing complication of etoposide therapy is the development of an unusual form of acute nonlymphocytic leukemia with a translocation in chromosome 11q23. At this locus is a gene (the MLL gene) that regulates the proliferation of pluripotent stem cells. The leukemic cells have the cytological appearance of acute monocytic or monomyelocytic leukemia. Another distinguishing feature of etoposide-related leukemia is the short time interval between the end of treatment and the onset of leukemia (1–3 years), compared to the 4- to 5-year interval for secondary leukemias related to alkylating agents, and the absence of a myelodysplastic period preceding leukemia (Pui et al., 1995). Patients receiving weekly or twice-weekly doses of etoposide, with cumulative doses greater than 2000 mg/m$^2$, seem to be at higher risk of leukemia.

**Teniposide**

Teniposide is administered intravenously. It has a multiphasic pattern of clearance from plasma: After distribution, a $t_{1/2}$ of 4 h and another $t_{1/2}$ of 10–40 h are observed. Approximately 45% of the drug is excreted in the urine; in contrast to etoposide, as much as 80% is recovered as metabolites. Anticonvulsants such as phenytoin increase the hepatic metabolism of teniposide and reduce systemic exposure. Dosage need not be reduced for patients with impaired renal function. Less than 1% of the drug crosses the blood-brain barrier. Teniposide is available for treatment of refractory ALL in children and is synergistic with cytarabine. Teniposide is administered...
by intravenous infusion for 5 days or twice weekly. The drug has limited utility and is given primarily for acute leukemia in children and monocytic leukemia in infants, as well as globlastoma, neuroblastoma, and brain metastases from small cell carcinomas of the lung. Myelosuppression, nausea, and vomiting is its primary toxic effects.

**Drugs of Diverse Mechanisms of Action**

**Bleomycin**
The bleomycins, a unusual group of DNA-cleaving antibiotics, are fermentation products of Streptomyces verticillus, comprising a family of peptide polyketides. The drug currently employed clinically is a mixture of two copper-chelating peptides, bleomycins A₃ and B₁, that differ only in their terminal amino acid. Because their toxicities do not overlap with those of other cytotoxic drugs and because of their unique mechanism of action, bleomycin maintains an important role in treating Hodgkin disease and testicular cancer.

**Mechanisms of Action and Resistance**
Bleomycin’s cytotoxicity results from its capacity to cause oxidative damage to the deoxyribose of thymidylate and other nucleotides, leading to single- and double-stranded breaks in DNA; the exact mechanism is unresolved. Bleomycin causes accumulation of cells in the G₂ phase of the cell cycle, and many of these cells display chromosomal aberrations, including chromatid breaks, gaps, fragments, and translocations. Bleomycin cleaves DNA by generating free radicals. In the presence of O₂ and a reducing agent, the metal-drug complex becomes activated and functions as a ferrous oxidase, transferring electrons from Fe²⁺ to molecular oxygen to produce oxygen radicals. Metallobleomycin complexes can be activated by reaction with the flavin enzyme, NADPH-CYP450 reductase. Bleomycin binds to DNA, and the activated complex generates free radicals that are responsible for abstraction of a proton at the 3’ position of the deoxyribose backbone of the DNA chain, opening the deoxyribose ring and generating a strand break in DNA. An excess of breaks generates cell death.

Bleomycin is degraded by a specific hydrolase found in various normal tissues, including liver. Hydrolase activity is low in skin and lung, perhaps contributing to the serious toxicity. Some bleomycin-resistant cells contain high levels of hydrolase activity. In other cell lines, resistance has been attributed to decreased uptake, repair of strand breaks, or drug inactivation by thiols or thiol-rich proteins.

**ADME**
Bleomycin is administered intravenously, intramuscularly, or subcutaneously or instilled into the bladder for local treatment of bladder cancer. Having a high molecular mass, bleomycin crosses the blood-brain barrier poorly. The elimination τ₀₅₀ is about 3 h. About two-thirds of the drug is excreted intact in the urine. Concentrations in plasma are greatly elevated in patients with renal impairment, and doses of bleomycin should be reduced in the presence of a ClCr less than 60 mL/min. Having a high molecular mass, bleomycin crosses the blood-brain barrier poorly. The elimination τ₀₅₀ is about 3 h. About two-thirds of the drug is excreted intact in the urine.

**Therapeutic Uses**
Bleomycin is given weekly or twice weekly by the intravenous, intramuscular, or subcutaneous route. A test dose of 2 units or less is recommended for patients with lymphoma. Myriad regimens are employed clinically, with bleomycin doses expressed in units. Total courses exceeding 250 mg should be given with caution, and usually only in high-risk testicular cancer treatment, because of a marked increase in the risk of pulmonary toxicity. Bleomycin also may be instilled into the pleural cavity in doses of 5–60 mg to ablate the pleural space in patients with malignant effusions. Bleomycin is highly effective against germ cell tumors of the testis and ovary. In testicular cancer, it is curative when used with cisplatin and vinblastine or cisplatin and etoposide. It is a component of the standard curative ABVD regimen for Hodgkin disease.

**Adverse Effects**
Because bleomycin causes little myelosuppression, it has significant advantages in combination with other cytotoxic drugs. However, it does cause a constellation of cutaneous toxicities, including hyperpigmentation, hyperkeratosis, erythema, even ulceration, and rarely, Raynaud phenomenon. Skin lesions may recur when patients are treated with other antineoplastic drugs. Rarely, bleomycin causes a flagellate dermatitis consisting of bands of pruritic erythema on the arms, back, scalp, and hands; this rash responds readily to topical corticosteroids.

The most serious adverse reaction to bleomycin is pulmonary toxicity, which begins with a dry cough, fine rales, and diffuse basal infiltrates on X-ray and may progress to life-threatening pulmonary fibrosis. Approximately 5%–10% of patients receiving bleomycin develop clinically apparent pulmonary toxicity, and about 1% die of this complication. Most who recover experience a significant improvement in pulmonary function, but fibrosis may be irreversible. Pulmonary function tests are not of predictive value for detecting early onset of this complication. The risk of pulmonary toxicity is related to total dose, with a significant increase in risk in total doses greater than 250 mg and in patients more than 40 years of age, in those with a ClCr less than 80 mL/min, and in those with underlying pulmonary disease; single doses of 30 mg/m² or more also are associated with an increased risk of pulmonary toxicity. Administration of high O₂ concentrations during anesthesia or respiratory therapy may aggravate or precipitate pulmonary toxicity in patients previously treated with the drug. There is no known specific therapy for bleomycin lung injury except for symptomatic management and standard pulmonary care. Steroids are of variable benefit, with greatest effectiveness in the earliest inflammatory stages of the lesion.

Other toxic reactions to bleomycin include hyperthermia, headache, nausea and vomiting, and a peculiar acute fulminant reaction observed in patients with lymphomas. This reaction is characterized by profound hyperthermia, hypotension, and sustained cardiorespiratory collapse; it does not appear to be a classical anaphylactic reaction and may be related to release of an endogenous pyrogen. This reaction has occurred in about 1% of patients with lymphomas or testicular cancer.

**Mitomycin**
Mitomycin has limited clinical utility, having been replaced by less toxic and more effective drugs, with the exception of the use in patients with anal cancers, for which it is potentially curative.

**Mechanisms of Action and Resistance**
After intracellular enzymatic or spontaneous chemical alteration, mitomycin becomes a bifunctional or trifunctional alkylating agent. The drug inhibits DNA synthesis and cross-links DNA at the N6 position of adenine and at the O6 and N7 positions of guanine. Attempts to repair DNA lead to strand breaks. Mitomycin is a potent radiosensitizer, teratogen, and carcinogen in rodents. Resistance has been ascribed to deficient activation, intracellular inactivation of the reduced Q form, and Pgp-mediated drug efflux.

**ADME**
Mitomycin is administered intravenously. It has a t₁/₂ of 25–90 min. The drug inhibits DNA synthesis and cross-links DNA at the N6 position of adenine and at the O6 and N7 positions of guanine. Attempts to repair DNA lead to strand breaks. Mitomycin is a potent radiosensitizer, teratogen, and carcinogen in rodents. Resistance has been ascribed to deficient activation, intracellular inactivation of the reduced Q form, and Pgp-mediated drug efflux.
Mitotane
Mitotane (o,p'-DDD), a compound chemically similar to the insecticides DDT and DDD, is used in the treatment of adrenal cortex carcinoma. The mechanism of action of mitotane has not been elucidated, but its relatively selective destruction of adrenocortical cells, normal or neoplastic, is well established. Administration of the drug causes a rapid reduction in the levels of adrenocorticosteroids and their metabolites in blood and urine, a response that is useful in both guiding dosage and following the course of hyperadrenocorticism (Cushing syndrome) resulting from an adrenal tumor or adrenal hyperplasia. It does not damage other organs.

Adverse Effects
Although the administration of mitotane produces anorexia and nausea in most patients, somnolence and lethargy in about 34%, and dermatitis in 15%–20%, these effects do not contraindicate the use of the drug at lower doses. Because this drug damages the adrenal cortex, administration of replacement doses of adrenocorticosteroids is necessary.

Trabectedin
Trabectedin is derived from the marine invertebrate tunicate Ecteinascidin turbinata. Trabectedin is an alkylating drug that binds to the minor groove of DNA, allowing the alkylation of the N2 position of guanine and bending the helix toward the major groove. The bulky DNA adduct is recognized by the transcription-coupled nucleotide excision–repair (NER) complex, and these proteins initiate attempts to repair the damaged strand, converting the adduct to a double-stranded break. Trabectedin has particular cytotoxic effects on cells that lack components of the Fanconi anemia complex or those that lack the ability to repair double-strand DNA breaks through homologous recombination (Soares et al., 2007). Unlike cisplatin and other DNA adduct–forming drugs, the activity of trabectedin requires the presence of intact components of NER, including XPG, which may be important for initiation of single breaks and attempts at adduct removal.

ADME
Approximately 40% of mitotane is absorbed after oral administration. Plasma concentrations of mitotane are still measurable for 6–9 weeks following discontinuation of therapy. Although the drug is found in all tissues, fat is the primary site of storage. A water-soluble metabolite of mitotane found in the urine constitutes 25% of an oral or parenteral dose. About 60% of an oral dose is excreted unchanged in the stool.

Therapeutic Uses
Mitotane initial daily oral doses are 2–6 g, usually in three or four divided portions. The maximal tolerated dose may vary from 2 to 16 g/d. Treatment should continue for at least 3 months; if beneficial effects are observed, therapy should be maintained indefinitely. Spirolactone should not be administered concomitantly because it interferes with the adrenal suppression produced by mitotane. Treatment with mitotane is indicated for the palliation of inoperable adrenocortical carcinoma, producing symptomatic benefit in 30%–50% of such patients.

Adverse Effects
Without dexamethasone pretreatment, trabectedin causes significant hepatic enzyme elevations and fatigue in at least one-third of patients. With the steroid, the increases in transaminase are less pronounced and rapidly reversible. Other toxicities include mild myelosuppression and, rarely, rhabdomyolysis.

1-Asparaginase
Malignant lymphoid cells depend on exogenous sources of l-asparagine. Thus, l-asparaginase (l-ASP) has become a standard agent for treating ALL.

Mechanism of Action
Most normal tissues synthesize l-asparagine in amounts sufficient for protein synthesis, but lymphocytic leukemias lack adequate amounts of asparagine synthase and derive the required amino acid from plasma. l-ASP, by catalyzing the hydrolysis of circulating asparagine to aspartic acid and ammonia, deprives these malignant cells of asparagine, leading to cell death. l-ASP is used in combination with other agents, including MTX, doxorubicin, vincristine, and prednisone, for the treatment of ALL and high-grade lymphomas. Resistance arises through induction of asparagine synthetase in tumor cells.

ADME and Therapeutic Use
Asparaginase is given intramuscularly or intravenously. After intravenous administration, Escherichia coli–derived l-ASP has a clearance rate from plasma of 0.035 mL/min/kg, a volume of distribution that approximates the volume of plasma in humans, and a t½ of 1 day. The enzyme is given in doses of 6000–10,000 IU every third day for 3–4 weeks. Pegaspargase, a preparation in which the enzyme is conjugated to 5000-Da units of monomethoxy polyethylene glycol, has a much longer plasma t½ (6–7 days); it is administered intramuscularly every 14 days, producing rapid and complete depletion of plasma and tumor cell asparagine for 21 days in most patients. Pegaspargase has much reduced immunogenicity (<20% of patients develop antibodies) and has been approved for first-line ALL therapy.

Intermittent dosage regimens and longer durations of treatment increase the risk of inducing hypersensitivity. In hypersensitive patients, neutralizing antibodies inactivate l-ASP. Not all patients with neutralizing antibodies experience clinical hypersensitivity, although the enzyme may be inactivated and therapy may be ineffective. In previously untreated ALL, pegaspargase produces more rapid clearance of lymphoblasts from bone marrow than does the E. coli preparation and circumvents the rapid antibody-mediated clearance seen with E. coli.
enzyme in relapsed patients. Asparaginase preparations only partially deplete CSF asparagine.

**Adverse Effects**

The 1-ASP toxicities result from its antigenicity as a foreign protein and its inhibition of protein synthesis. Hypersensitivity reactions, including urticaria and full-blown anaphylaxis, occur in 5%–20% of patients and may be fatal. In these patients, pegaspargase is a safe and effective alternative. So-called silent enzyme inactivation by antibodies occurs in a higher percentage of patients than overt hypersensitivity and may be associated with a negative clinical outcome, especially in high-risk patients with ALL.

Other toxicities result from inhibition of protein synthesis in normal tissues (e.g., hyperglycemia due to insulin deficiency, clotting abnormalities due to deficient clotting factors, hypertriglyceridemia due to effects on lipoprotein production, hypoalbuminemia). Pancreatitis also has been observed. The clotting problems may take the form of spontaneous thrombosis or, less frequently, hemorrhagic episodes. Brain magnetic resonance imaging studies should be considered in patients treated with 1-ASP who present with seizures, headache, or altered mental status. Intracranial hemorrhage in the first week of 1-ASP treatment is an infrequent but devastating complication. 1-ASP also suppresses immune function. 1-ASP terminates the antitumor activity of MTX when given shortly after the antimetabolite. By lowering serum albumin concentrations, 1-ASP may decrease protein binding and accelerate plasma clearance of other drugs.

**Hydroxyurea**

Hydroxyurea inhibits RNR and has unique and diverse biological effects as an antileukemic drug, radiation sensitizer, and an inducer of HbF in patients with sickle cell disease. It is orally administered, and its toxicity is modest and limited to myelosuppression.

**Mechanisms of Action and Resistance**

Hydroxyurea inhibits the enzyme ribonucleotide reductase (RNR), which catalyzes the reductive conversion of ribonucleotides to deoxyribonucleotides, a rate-limiting step in the biosynthesis of DNA. HU binds iron molecules that are essential for activation of a tyrosyl radical in the catalytic subunit of RNR. The drug is specific for the S phase of the cell cycle, during which RNR concentrations are maximal. HU produces arrest at or near the G1-S interface through both p53-dependent and -independent mechanisms. Because cells are highly sensitive to irradiation at the G1-S boundary, HU and irradiation cause synergistic antitumor effects. Through depletion of deoxyribonucleotides, HU potentiates the antiproliferative effects of DNA-damaging agents such as cisplatin, alkylating agents, or topoisomerase II inhibitors and facilitates the incorporation of antimetabolites such as Ara-C, gemcitabine, and fluoraraban into DNA. It also promotes degradation of the p21 cell-cycle checkpoint and thereby enhances the effects of HDAC inhibitors in vitro (Kramer et al., 2008).

Hydroxyurea is the primary drug for improving control of sickle cell (HBS) disease in adults and for inducing HbF in patients with thalassemia HbC and HbC/S. It reduces vaso-occlusive events, painful crises, hospitalizations, and the need for blood transfusions in patients with sickle cell disease. The mechanism of stimulated HbF production is uncertain. HU stimulates NO production, causing nitrosylation of low-molecular-weight GTPases, a process that stimulates γ-globin production in erythroid precursors. Another property of HU that may be therapeutically relevant is its capacity to reduce t-selenocysteine and thereby to reduce adhesion of red cells and neutrophils to vascular endothelium. Also, by suppressing the production of neutrophils, it decreases their contribution to vascular occlusion. Tumor cells become resistant to HU through increased synthesis of the catalytic subunit of RNR, thereby restoring enzyme activity.

**ADME**

The oral bioavailability of HU is 80%–100%; comparable plasma concentrations are seen after oral or intravenous dosing. HU disappears from plasma with a t1/2 of 3.5–4.5 h. The drug readily crosses the blood-brain barrier; significant quantities appear in human breast milk. From 40% to 80% of the drug is recovered in the urine within 12 h after administration. It is advisable to modify initial doses for patients with renal dysfunction.

**Therapeutic Uses**

In cancer treatment, HU is used alone or in combination with other drugs with two dosage schedules: (1) intermittent therapy administered orally as a single dose (~80 mg/kg) every third day or (2) continuous therapy administered as a single daily dose (20–30 mg/kg). In patients with essential thrombocythemia and in sickle cell disease, HU is given in a daily dose of 15 mg/kg, adjusting that dose upward or downward according to blood counts. The neutrophil count responds within 1–2 weeks to discontinuation of the drug. In treating subjects with sickle cell and related diseases, a neutrophil count of at least 2500 cells/mL should be maintained. Treatment typically is continued for 6 weeks to determine effectiveness; if satisfactory results are obtained, therapy can be continued indefinitely, although leukocyte counts at weekly intervals are advisable.

The principal use of HU has been as a myelosuppressive agent in various myeloproliferative syndromes, particularly CML, polycythemia vera, myeloid metaplasia, and essential thrombocytosis, for controlling high platelet or white cell counts. Many of the myeloproliferative syndromes harbor activating mutations of Jak2, a gene that is downregulated by HU. In essential thrombocythemia, it is the drug of choice for patients with a platelet count greater than 1.5 million cells/mm3 or with a history of arterial or venous thrombosis. In CML, HU has been largely replaced by imatinib (see Chapter 67). HU is a potent radiosensitizer as a consequence of its inhibition of RNR and has been incorporated into several treatment regimens with concurrent irradiation (i.e., cervical carcinoma, primary brain tumors, head and neck cancer, non–small cell lung cancer).

**Adverse Effects**

Leukopenia, anemia, and occasionally thrombocytopenia are the major toxic effects; recovery of the bone marrow is prompt if the drug is discontinued for a few days. Other adverse reactions include a desquamative interstitial pneumonitis, GI disturbances, mild dermatological reactions, and, more rarely, stomatitis, alopecia, and neurological manifestations. Increased skin and fingernail pigmentation may occur, as well as painful leg ulcers, especially in elderly patients or in those with renal dysfunction. HU does not increase the risk of secondary leukemia in patients with myeloproliferative disorders or sickle cell disease. It is a potent teratogen in animals and should not be used in women with childbearing potential.

**Retinoids**

One of the hallmarks of malignant transformation is a block in differentiation. A number of chemical entities (vitamin D and its analogues, retinoids, benzamides and other inhibitors of HDAC [see Chapter 67], various cytotoxic and biological agents, and inhibitors of DNA methylation) can induce differentiation in tumor cell lines. The most important of these for cancer treatment are retinoids, in particular tretinoin (ATRA), which induces a high rate of complete remission in patients with APL as a single agent and, in combination with anthracyclines, cures most patients with this disease. The biology and pharmacology of retinoids are discussed in detail in Chapter 70.

**Tretinoin (ATRA)**

**Mechanism of Action.** Under physiological conditions, the RARA dimerizes with the retinoid X receptor to form a complex that binds ATRA tightly. ATRA binding displaces a repressor from the transcriptional complex and alters the expression of genes that control differentiation of cells of multiple lineages. Most APLs are characterized by a chromosomal translocation of the RARA gene on chr17 and fusion with the PML on

Brunton_Ch66_p1167-p1202.indd 1195
08/09/17 1:33 PM
Mechanism of Action

The basis for ATO's antitumor activity remains uncertain. APL cells have high levels of ROS and are quite sensitive to further ROS induction. ATO inhibits thioredoxin reductase and thereby generates ROS. It inactivates glutathione and other sulfhydryls that scavenge ROS and thereby aggravates ROS damage. Cells exposed to ATO also upregulate p53, Jum Kinase, and caspases associated with the intrinsic pathway of apoptosis and downregulate antiapoptotic proteins such as bcl-2 (Figure 13–15). ATO's cytotoxic effects are antagonized by cell survival signals emanating from activation of components of the PI3 kinase cell survival pathway, including PKB, S6 kinase, and mTOR (Figures 3–16 and 67–4). ATO also induces differentiation of leukemic cell lines in experimental and human leukemias.

ADME

Arsenic trioxide is well absorbed orally but in cancer treatment is administered as a 2-h daily intravenous infusion in dosages of 0.15 mg/kg/d for up to 60 days, until remission is documented. The drug enters cells via one of several glucose transporters. The primary mechanism of elimination is through enzymatic methylation. Multiple methylated metabolites (Figure 71–9) form rapidly and are excreted in urine. Less than 20% of administered drug is excreted unchanged in the urine. No dose reductions are indicated for hepatic or renal dysfunction.

ADME and Therapeutic Use

Oral administration of ATRA is 45 mg/m²/d until 30 days after remission is achieved (maximum course of therapy is 90 days). ATRA as a single agent reverses the hemorrhagic diathesis associated with APL and induces a high rate of temporary remission. ATRA in combination with an anthracycline induces remission with 80% or greater relapse-free long-term survival.

ATO is cleared by a CYP3A4-mediated elimination with a t½ of less than 1 h. Treatment with inducers of CYP3A4 leads to more rapid drug disappearance and resistance to ATRA. Inhibitors of CYPs, such as antifungal imidazoles, block ATRA degradation and may lead to hypercalcemia and renal failure, which respond to diuresis, bisphosphonates, and ATRA discontinuation. Corticosteroids and chemotherapy sharply decrease the occurrence of “retinoic acid syndrome,” which is characterized by fever, dyspnea, weight gain, pulmonary infiltrates, and pleural or pericardial effusions. When used as a single agent for remission induction, especially in patients with more than 5000 leukemic cells/mm³ in the peripheral blood, ATRA induces an outpouring of cytokines and mature-appearing neutrophils of leukemic origin. These cells express high concentrations of integrins and other adhesion molecules on their surface and clog small vessels in the pulmonary circulation, leading to significant morbidity in 15%–20% of patients. The syndrome of respiratory distress, pleural and pericardial effusions, and mental status changes may have a fatal outcome. Retinoids also cause dry skin, cheilitis, reversible hepatic enzyme abnormalities, bone tenderness, pseudotumor cerebri, hypercalcemia, and hyperlipidemia.

Arsenic Trioxide

Arsenic trioxide (As₂O₃), known as ATO, is a highly effective treatment of relapsed APL, producing complete responses in more than 85% of such patients. The chemistry and toxicity of arsenic are considered in Chapter 71.

| Mechlorethamine | • Hodgkin lymphoma  
• Topical: cutaneous T-cell lymphoma  
• Acute and chronic lymphocytic leukemia; Hodgkin lymphoma; non-Hodgkin lymphoma; multiple myeloma; neuroblastoma; breast, ovary, Wilms tumor; soft-tissue sarcoma  
• Autoimmune disease (Wegener granulomatosis, rheumatoid arthritis, nephrotic syndrome) | • Vascular damage during injection due to vesicant properties  
• Oral or intravenous administration  
• Active alkylating moieties generated through hepatic metabolism  
• Nephrotoxic and urotoxic metabolite, acrolein; severe hemorrhagic cystitis in high-dose regimens; prevented by MESNA  
• Provide vigorous hydration during high-dose treatment  
• Elimination not affected by renal dysfunction; reduce dose in patients with hepatic dysfunction |
| Cyclophosphamide | • Germ cell testicular cancer  
• Pediatric and adult sarcoma  
• High-dose chemotherapy with bone marrow rescue | • See cyclophosphamide  
• Can cause neurotoxicity (including seizures)  
• Methylene blue treatment of CNS toxicity possibly useful |
| Ifosfamide | • Multiple myeloma | • Oral and intravenous administration |
| Melphalan | • High-dose chemotherapy regimen with bone marrow transplantation | • Oral administration |
| Chlorambucil | • Chronic lymphocytic leukemia | • Lacks cross-resistance with other classical alkylators |
| Bendamustine | • Non-Hodgkin lymphoma  
• Chronic lymphocytic leukemia | |
| **Alkyl Sulfonate: DNA alkylation** |
| Busulfan | • Chronic myelogenous leukemia  
• High-dose chemotherapy regimen with bone marrow transplantation | • Oral administration  
• Adverse effects: prolonged (up to years) pancytopenia; suppression of stem cells; seizures; ↑ clearance of phenytoin; hepatic VOD |
| **Nitrosoureas: DNA alkylation** |
| Carmustine (BCNU) | • Malignant gliomas  
• Hodgkin lymphoma; non-Hodgkin lymphoma | • Vascular damage during injection due to vesicant properties  
• Profound and delayed myelosuppression |
| Streptozocin (streptozotocin) | • Malignant pancreatic insulinoma  
• Carcinoid | • Frequent renal toxicity, sometimes renal failure |
| **Methylhydrazine Derivatives: Monofunctional DNA alkylation** |
| Procarbazine (W-methylhydrazine, MH) | • Hodgkin lymphoma  
• Gliomas | • Greater capacity for mutagenesis and carcinogenesis than bifunctional alkylators (e.g., cyclophosphamide) |
| **Triazenes: Methyl transfer to DNA** |
| Dacarbazine (DTIC) | • Hodgkin lymphoma; soft-tissue sarcomas  
• Melanoma | • Intralesional administration  
• Activation by hepatic CYPs  
• Adverse effects: nausea, vomiting  
• Rare hepatotoxicity and neurotoxicity |
| Temozolomide | • Malignant gliomas | • Oral administration  
• Combined with radiation therapy  
• Greater capacity for mutagenesis and carcinogenesis than bifunctional alkylators; more active in MGMT-deficient tumors |
| **Platinum Coordination Complexes: Form covalent metal adducts with DNA** |
| Cisplatin | • Testicular, ovarian, bladder, esophageal, gastric, lung, head and neck, anal, and, breast cancer | • Intralesional administration  
• Adverse effects:  
  • Nephrotoxicity (reduce by forced pretreatment hydration, diuresis, and use of amifostine)  
  • Ototoxicity (tinnitus, high-frequency hearing loss)  
  • Nausea and vomiting (antidote, aperiprant)  
  • Peripheral sensory and motor neuropathy (may worsen after discontinuation; may be aggravated by taxane treatment)  
  • Drug resistance due to loss of mismatch repair proteins |

</table>

*For drugs that are subject to hepatic metabolism by CYP enzymes, drug exposure of a patient can be affected by coadministration of inhibitors or inducers of CYP3A4 and can then reduce efficacy or increase side effects.

*Embryo-fetal toxicity: Consider that all of these drugs can cause fetal harm. Advise women of the potential risk to a fetus and to avoid pregnancy while taking the drug and for 1 month after cessation of therapy. Advise men to avoid fathering a child during the same time period. Avoid lactation during therapies.

</table>
Development of targeted therapies for treating cancer relies on the continuing process of discovery of molecular changes that drive malignant progression of human cancers. A rapidly growing number of drugs are being developed to block oncogenic pathways that lead to dysregulated cancer cell growth and survival. Targeted therapy may be combined with classical cytotoxic cancer drugs described in Chapter 66 for improved efficacy. Growth factor receptors and downstream signaling molecules are amongst the most actively explored targets for cancer drug discovery. The drivers of cancer growth are oncogenic pathways in malignant cells themselves (e.g., mutant receptors and kinases), the reaction of the tumor microenvironment (e.g., angiogenesis), and the escape of malignant cells from the host’s immune surveillance (Hanahan and Weinberg, 2011). The discussion of drugs in this chapter is organized into sections focusing on these drivers of cancer growth:

I. Growth factors and receptors in cancer cells
II. Intracellular kinases in cancer cells
III. Tumor-host interactions reflected in aberrant tumor angiogenesis
IV. Restoring immune recognition of cancer cells
V. Other drugs and targets that control cancer cell behavior

The primary tools for targeting oncogenic pathways are monoclonal antibodies that recognize cell surface or shed antigens (e.g., growth factor receptors or receptor ligands) and small molecules that can enter cells and engage intracellular targets, many of them kinases. Two classes of drugs have very different pharmacological properties (see Box).

### Inhibitors of Epidermal Growth Factor Receptor (EGFR) Function

#### Background

The EGFR belongs to the ErbB family of transmembrane receptor tyrosine kinases also known as ErbB1 or HER1 (human EGFR 1). EGFR is essential for the growth and differentiation of epithelial cells. Ligand binding to the extracellular domain of EGFR family members causes receptor dimerization and stimulates the protein tyrosine kinase activity of the intracellular domain, resulting in autophosphorylation of several Tyr residues located in the C-terminal tail of the receptor monomers. These phosphotyrosines provide interaction sites for a variety of adapter proteins, resulting in stimulation of signaling pathways, including MAPK, PI3K/Akt, and STAT pathways (see Figure 67–1).

Two separate classes of drugs that target the EGFR pathway are important in the therapy of solid tumors: protein tyrosine kinase inhibitors and inhibitors of extracellular ligand binding. EGFR TKIs (erlotinib, gefitinib, afatinib, osimertinib) bind to the intracellular kinase domain and inhibit the enzymatic function of an EGFR. Monoclonal antibodies (cetuximab, panitumumab, nectumumab) recognize the extracellular domain of the EGFR, inhibit ligand-induced signaling, and can elicit an immune response. In epithelial cancers, overexpression of the EGFR is a common finding, and mutational activation of the EGFR (e.g., in 10%–40% of NSCLCs) creates a dependence on EGFR signaling. The most common EGFR mutations are in-frame deletions in exon 19 or leucine-to-arginine point mutations (L858R) in exon 21 that cause conformational changes and constitutive activation of the kinase. First- (erlotinib, gefitinib) and second- (afatinib) generation drugs are available that inhibit EGFR kinase activity driven by these mutations. Resistant cancer cell subpopulations that emerge during treatment with first- and second-generation inhibitors are usually sensitive to the third-generation inhibitor osimertinib (Figure 67–1).

#### Protein Tyrosine Kinase Inhibitors of EGFR

**Erlotinib**

**Mechanism of Action.** Erlotinib is a reversible inhibitor of the EGFR tyrosine kinase, competitively inhibiting ATP binding at the active site of the kinase. Erlotinib has an IC_{50} of 2 nM for EGFR kinase activity. By comparison, for many protein kinases, the K_{i} for ATP at the substrate site is in the range of 20 μM.

**ADME.** Erlotinib is about 60% absorbed after oral administration. Peak plasma levels occur after 4 h. Erlotinib has a t_{1/2} of 36 h and is metabolized by CYP3A4 and to a lesser extent by CYPs 1A2 and 1A1.

**Therapeutic Uses.** Erlotinib is approved for treatment of patients with advanced or metastatic NSCLC after failure of platinum-based treatment. In newly diagnosed NSCLC, erlotinib is approved in patients with EGFR mutations only (Figure 67–1). Erlotinib in combination with gemcitabine is also approved for the treatment of patients with locally advanced, unresectable, or metastatic pancreatic cancer.

### Two Classes of Pathway-Targeted Cancer Drugs

1. **Monoclonal Antibodies:** Monoclonal antibodies kill tumor cells by blocking cell surface receptor function, by recruiting immune cells and complement to the antigen–antibody complex, and by modulating immune cell function. Also, they may be armed to carry toxins or radionuclides to the cells of interest, thereby enhancing their cytotoxic effects. A monoclonal antibody is generally specific for a single antigen, such as an epitope in a growth factor receptor; has a long plasma t_{1/2}; and requires only intermittent parenteral administration.

2. **Small Molecules:** Small molecules may attack the same targets as monoclonal antibodies but can exert their effect by entering cells. Small molecules often inhibit multiple enzymes with different selectivities and thus are likely to have a broader spectrum of targets and produce a broader spectrum of desired effects, off-target effects, and adverse effects than monoclonal antibodies. Many small-molecule drugs have elimination half-lives of 12 to 24 h and typically require at least daily oral administration. For small-molecule drugs that are metabolized by hepatic CYPs, the concomitant use of strong CYP inhibitors (e.g., ketoconazole, nefazodone, clarithromycin, gemfibrozil, cobicistat) or inducers (e.g., rifampin, phenytoin, carbamazepine, phenobarbital, St John’s wort) can lead to increased adverse effects due to reduced drug elimination or to reduced efficacy due to accelerated clearance. The small-molecule inhibitors mentioned in this chapter, mostly protein kinase inhibitors, end with the syllable “ib.” More than 130 novel TKIs are currently being evaluated in different clinical phases (Neul et al., 2016).
In treating cancers, the selection of the most appropriate treatment(s), dose, and dose intervals as well as the management of adverse effects requires specialized knowledge and a team effort. In addition, cancer treatment regimens are undergoing frequent updates due to findings in ongoing clinical trials. The availability of drugs with new mechanisms of action (e.g., immune checkpoint inhibitors), good target selectivity (e.g., kinase inhibitors), efficacy in specific cancers, and different adverse effect profiles permits the use of new drug combinations and regimens. The chapters on the pharmacotherapy of cancer focus on mechanism of action, ADME, and adverse effects, with less emphasis on treatment regimens. There are several excellent sources of up-to-date treatment information. The U.S. FDA provides authoritative information on approved drugs online (http://www.accessdata.fda.gov/scripts/cder/daf/). Detailed treatment guidelines for most cancers are available from the NCCN, an alliance of cancer centers that establishes evidence-based guidelines for cancer treatment. The NCCN guidelines are continuously updated to reflect new information that may alter clinical practice. The guidelines can be accessed online (https://www.nccn.org/professionals/physician_gls/f_guidelines.asp).

This table provides examples that illustrate the complexities of current treatment for two cancers: HER2+ breast cancer and advanced colorectal cancer.

| HER2-Positive Breast Cancer | Day 1: Doxorubicin 60 mg/m² IV  
Day 1: Cyclophosphamide 600 mg/m² IV  
Repeat cycle every 21 days for 4 cycles  
Followed by  
Day 1: Pertuzumab 840 mg IV followed by 420 mg IV  
Day 1: Trastuzumab 8 mg/kg IV followed by 6 mg/kg IV  
Days 1, 8, and 15: Paclitaxel 80 mg/m² IV  
Repeat cycle every 21 days for 4 cycles  
Day 1: Trastuzumab 6 mg/kg IV  
Repeat cycle every 21 days to complete 1 year of trastuzumab therapy  
Cardiac monitoring at baseline and 3-month intervals |
| Advanced or Metastatic Colorectal Cancer RAS wild-type | Day 1: Oxaliplatin 85 mg/m² IV over 2 h  
Day 1: Leucovorin 400 mg/m² IV over 2 h  
Days 1–3: 5FU 400 mg/m² IV bolus on day 1, then 1200 mg/m²/d × 2 days (total 2400 mg/m² over 46–48 h) IV continuous infusion  
Repeat cycle every 2 weeks, plus  
Cetuximab 400 mg/m² IV over 2 h for the first infusion, then 250 mg/m² IV over 60 min weekly.  
OR  
Day 1: Cetuximab 500 mg/m² IV over 2 h every 2 weeks |

**Adverse Effects and Drug Interactions.** The most common adverse reactions (≥20%) are rash, diarrhea, anorexia, fatigue, dyspnea, nail disorders, nausea, and vomiting. Serious adverse reactions include severe rash (>10%). Fatal interstitial lung disease occurs with a frequency of 0.7%–2.5%, and fatal hepatic failure has been reported, particularly in patients with baseline hepatic dysfunction. Other rare but serious toxicities include GI perforation, renal failure, arterial thrombosis, microangiopathic hemolytic anemia, hand-foot skin reaction, and corneal perforation or ulceration. Erlotinib therapy may cause rare cases of Stevens-Johnson syndrome/toxic epidermal necrolysis.

Concurrent use of proton pump inhibitors decreases the bioavailability of erlotinib by 50%. Plasma levels can vary due to drug interactions with inducers or inhibitors of CYP3A4. Patients using warfarin may experience poorer extrinsic coagulation (elevated INR) while taking erlotinib. Smoking accelerates metabolic clearance of erlotinib and may decrease its antitumor effects.

**Gefitinib**

**Mechanism of Action.** Gefitinib inhibits the EGFR tyrosine kinase by competitive blockade of ATP binding with an IC₅₀ of 20–60 nM for the kinase activity.

**ADME.** Oral bioavailability is about 60%; peak plasma concentrations are achieved within 3–7 h. Absorption of gefitinib is not significantly altered by food but is reduced by drugs that cause elevations in gastric pH. Metabolism of gefitinib is predominantly via CYP3A4, with a terminal t½ of 41 h. Inducers of CYP3A4 activity decrease gefitinib plasma concentrations and efficacy; conversely, CYP3A4 inhibitors increase plasma concentrations.

**Therapeutic Uses.** Gefitinib is approved for treatment of patients with metastatic NSCLC with EGFR mutations (Figure 67–1).

**Adverse Effects and Drug Interactions.** Diarrhea and skin reactions occur in more than 20% of patients. In addition to pustular/papular rash,
Afatinib is a second-generation, orally bioavailable, irreversible inhibitor of EGFR (HER1) and HER2 receptor kinases with IC50 values of 0.5 and 14 nM, respectively.

**Mechanism of Action.** Afatinib is a substrate of Pgp and coadministration of Pgp-modulating drugs can alter effective drug concentrations of afatinib. Afatinib is approved for the first-line treatment of patients with metastatic NSCLC with EGFR mutations (see Figure 67–1) and patients with metastatic squamous NSCLC that have progressed subsequent to platinum-based chemotherapy.

**Adverse Effects and Drug Interactions.** Most common adverse effects are diarrhea and skin rash/naevoid dermatitis, stomatitis, as well as hand-foot skin reactions. Also observed are interstitial lung disease, liver function abnormalities, and left ventricular dysfunction.

### Resistance to Gefitinib, Erlotinib, and Afatinib

The majority of tumors with activating mutations in the EGFR initially respond to these kinase inhibitors of the first (gefitinib, erlotinib) and second generation (afatinib). Eventually, however, the tumors progress. Approximately 60% of NSCLC acquire a second EGFR mutation in the so-called EGFR gatekeeper residue T790M (see Figure 67–1) that prevents binding of these inhibitors to the kinase domain. Osimertinib, a third-generation inhibitor designed to recognize the T790M-mutant EGFR, is described next. Other mechanisms of resistance include mutational activation of downstream signaling molecules such as KRAS or activation of parallel signaling pathways, for example, through MET amplification, EML4-ALK translocation (see Figure 67–2), and small cell lung cancer transformation. ALK and MET kinase inhibitors are described in material that follows (Smit and Baas, 2015).

### Osimertinib

**Mechanism of Action.** Osimertinib is a third-generation, orally bioavailable, irreversible inhibitor of T790M-mutant EGFR, with an IC50 value of 10 nM. The T790M gatekeeper mutation is often acquired after prior treatment with other EGFR kinase inhibitors (see previous discussion). Very sensitive detection methods can identify the presence of T790M in up to 30% of untreated patients, suggesting preexisting resistant subpopulations (see Chapter 65, Figure 65–3).

**ADME.** The mean t1/2 of osimertinib is 48 h. Osimertinib is a substrate of CYP3A4. The drug is primarily eliminated in the feces and to a lesser extent in the urine. Concurrent administration of inducers of CYP3A may necessitate an increase in the dose.

**Therapeutic Uses.** Osimertinib is approved for metastatic NSCLC that has progressed after prior EGFR TKI treatment and is positive for the EGFR T790M mutation. Genotyping of tumor biopsies for the T790M mutation is required after resistance develops. Recent studies have shown that noninvasive genotyping of DNA shed from tumor cells into the bloodstream may be feasible after extracting cell-free DNA from patient serum samples (Oxnard et al., 2016). Response rates are greater than 60% in patients with metastatic NSCLC. However, with osimertinib treatment acquired resistance occurs, most commonly manifested by the appearance of a third mutation, C797S. The mutation of Cys797 to Ser797 prevents formation of the potency-conferring covalent bond of the inhibitor (Thress et al., 2015). Inhibitors of C797S-mutant EGFR are under development for combination treatment with an EGFR-targeted antibody (Jia et al., 2016).

**Adverse Effects and Drug Interactions.** The most common adverse effects after osimertinib treatment are diarrhea and skin rash; however, these are much less common and severe than for first- and second-generation inhibitors, presumably because the activity on wild-type EGFR is limited with third-generation inhibitors. Also observed are interstitial lung disease, QTc prolongation, and left ventricular dysfunction.

### Antibody Inhibitors of EGFRs

**Cetuximab**

**Mechanism of Action.** Cetuximab is a recombinant, chimeric human/mouse IgG antibody that binds to the extracellular domain III of EGFR (Figure 67–1) and prevents ligand-dependent signaling and receptor dimerization, thereby blocking cell growth and survival signals. Cetuximab can also mediate ADCC against tumor cells that express high levels of EGFR.

**ADME.** Cetuximab exhibits nonlinear pharmacokinetics. A single loading dose of cetuximab intravenously is followed by weekly...
maintenance doses for the duration of treatment. Following intravenous administration, steady-state levels are achieved by the third weekly infusion. The volume of distribution approximates the intravascular space. The half-life of cetuximab is about 5 days.

**Therapeutic Uses.** Antibodies targeting EGFR show a different spectrum of antitumor activity than EGFR TKIs, in part due to the additional ADCC of antibodies toward tumor cells. Cetuximab and related antibodies are used to treat patients with metastatic colon cancers and HNSCC.

In colon cancer, cetuximab enhances the effectiveness of chemotherapy in patients with KRAS wild-type but not KRAS-mutant tumors (Van Cutsem et al., 2009). A combination of cetuximab with FOLFIRI (see Chapter 66) is typically used to treat patients with KRAS wild-type tumors that express EGFR. Cetuximab is also used as a single agent in patients who cannot tolerate irinotecan-based therapy and in patients with cancers that are resistant to oxaliplatin, irinotecan, and 5FU.

In HNSCC, cetuximab is used in combination with radiation or with platinum complex-based chemotherapy (e.g., cisplatin; see Chapter 66) for locally or regionally advanced HNSCC. Cetuximab is also indicated as a monotherapy for patients with metastatic or recurrent HNSCC who fail platinum-based chemotherapy.

**Adverse Effects.** Antibodies targeting EGFR have an adverse effect profile similar to that of first-generation EGFR protein tyrosine kinase inhibitors. Acneiform rash in the majority of patients, pruritus, nail changes, headache, and less frequently diarrhea are the most common adverse reactions. Rare but serious adverse effects include infusion reactions (1–3% of patients), cardiopulmonary arrest (2%–3%), interstitial lung disease, and serum electrolyte imbalances, including hypomagnesemia. During pregnancy, cetuximab may be transmitted to the developing fetus and has the potential to cause fetal harm.

**Other EGFR Antibodies**

**Panitumumab**

Panitumumab is a recombinant, fully humanized IgG1 antibody that binds to the extracellular domain III of the EGFR and prevents ligand-dependent signaling. It is FDA approved for the treatment of EGFR-expressing mCRC in combination with chemotherapy and as monotherapy after disease progression following chemotherapy regimens containing fluoropyrimidine, oxaliplatin, and irinotecan (Saltz et al., 2006). Although panitumumab effectively inhibits EGFR signaling similarly to cetuximab, it is less effective at triggering cellular immune mechanisms that may be crucial for effective therapy of HNSCC (Trivedi et al., 2016).

**ADME; Adverse Effects.** Panitumumab exhibits nonlinear pharmacokinetic characteristics. Following intravenous administration every 2 weeks, steady-state levels are achieved by the third infusion. The mean t1/2 is 7.5 days. 

**Necitumumab**

Necitumumab is a recombinant human IgG1 monoclonal antibody that binds to the extracellular domain of the EGFR. It is approved for first-line treatment of patients with metastatic, squamous NSCLC in combination with gemcitabine and cisplatin. Necitumumab is administered intravenously every 3 weeks prior to chemotherapy. Adverse effects are similar to those of cetuximab.
HER2/Neu Inhibitors

Human epidermal growth factor receptor 2 (also named Neu or ErbB2) is a member of the HER family, which includes also EGFR (HER1), HER3, and HER4 (Figure 67–2). The fixed conformation of the extracellular domain of HER2 resembles the ligand-activated state of the other HER family members and explains its unique function as a coreceptor that does not require ligand activation. In addition, due to this conformation, the overexpression of wild-type HER2 is sufficient to activate the intracellular tyrosine kinase and oncogenic signaling even in the absence of activating mutations, coreceptors, or ligands. Overexpression of HER2 is found in 20% to 30% of human breast cancers due to gene amplification on chromosome 17 and results in more aggressive tumors, lower response rates to hormonal therapies, and higher risk of disease recurrence after treatment.

Trastuzumab

Mechanism of Action

Trastuzumab is a humanized IgG1 monoclonal antibody that binds to the extracellular domain IV of HER2 (Figure 67–2), inhibiting hetero- and homodimerization and signal transduction. In addition, binding of trastuzumab to HER2 overexpressing cells can induce antibody–dependent, immune cell–mediated cytotoxicity. HER2 protein overexpression or gene amplification are predictive of response to HER2-targeted therapies (Wolff et al., 2013).

ADME

Trastuzumab has dose-dependent pharmacokinetics with a mean t1/2 of 5.8 days on a weekly maintenance dose with alternative dosing every 3 weeks. Steady-state levels are achieved between 16 and 32 weeks.

Therapeutic Uses

Trastuzumab is approved for HER2-overexpressing breast and gastric cancer. It is used in combination with cytotoxic chemotherapeutics such as taxanes as initial treatment or as a single agent following relapse of disease after cytotoxic chemotherapy (Chapter 66).

Adverse Effects and Precautions

Acute adverse effects after infusion of trastuzumab are typical for monoclonal antibodies and can include fever, chills, nausea, dyspnea, and rashes. The most serious toxicity of trastuzumab is heart failure. Cardiotoxicity is caused by interruption of HER2/4 heterodimer signaling in cardiomyocytes, signaling that is essential for the maintenance of contractile function. The cardiotoxic potential was predicted from gene inactivation studies (“knockouts”) in mice, which showed that mice lacking HER2, HER4, or HER ligands developed dilated cardiomyopathy and heart failure. Thus, baseline electrocardiogram and cardiac ejection fraction measurement should be obtained before initiating treatment with trastuzumab to rule out underlying heart disease. Clinical monitoring for symptoms of congestive heart failure as well as periodic determination of LVEF during and after the course of therapy is recommended. When trastuzumab is used as a single agent, fewer than 5% of patients will experience a decrease in LVEF; and about 1% will have clinical signs of congestive failure. However, left ventricular dysfunction occurs in up to 20% of patients who receive a combination of doxorubicin and trastuzumab, reflecting the added cardiotoxicity of doxorubicin. In contrast, the risk of cardiac toxicity is greatly reduced with the recommended combination of trastuzumab with taxanes.

Pertuzumab

Mechanism of Action

Pertuzumab is a humanized monoclonal antibody directed against the extracellular receptor dimerization domain II of HER2 that is distinct from domain IV targeted by trastuzumab (Figure 67–2). Pertuzumab prevents ligand-dependent heterodimerization of other HER family members with HER2 and thus inhibits ligand-induced signaling, cell growth, and survival. In addition to the inhibition of receptor heterodimerization, binding of pertuzumab to HER2 overexpressing cells can induce antibody-dependent, immune cell–mediated cytotoxicity.

ADME

The median half-life of pertuzumab is 18 days; after an initial loading dose, maintenance doses are administered every 3 weeks.

Therapeutic Use

Preclinical studies with HER2-overexpressing human tumor cells grown as xenograft tumors in mice showed that the combination of pertuzumab and trastuzumab enhanced antitumor activity. In patients with HER2-positive metastatic breast cancer, the addition of pertuzumab to trastuzumab and docetaxel increases the median overall survival by 15.7 months (Swain et al., 2015). Use of pertuzumab is approved for the treatment of patients with HER2-positive, locally advanced, inflammatory, or early stage breast cancer in combination with trastuzumab and docetaxel.

Adverse Effects

Cardiotoxicity is similar to that of trastuzumab, and combinations with cardiotoxic anthracyclines are not indicated (Slamon et al., 2001). On the other hand, the combination of pertuzumab and trastuzumab does not cause any increase in cardiac toxicity (Swain et al., 2015). Based on its mechanism of action, pertuzumab can cause fetal harm when administered to a pregnant woman, and this risk should be weighed against the potential benefit.

Lapatinib

Mechanism of Action; ADME

Lapatinib is an orally bioavailable, small-molecule inhibitor of the EGFR and HER2 tyrosine kinases with an IC50 of about 10 nM. Lapatinib is metabolized by CYP3A4 with a plasma t1/2 of 14 h. Concurrent administration of inducers and inhibitors of CYP3A4 may necessitate adjustment of the dose.

Therapeutic Uses; Adverse Effects

Lapatinib in combination with capecitabine is approved for the treatment of patients with metastatic HER2-positive and trastuzumab-refractory breast cancer. Lapatinib is also used in combination with the aromatase inhibitor letrozole (see Chapter 68) to treat postmenopausal women with hormone receptor–positive, metastatic breast cancer that overexpresses HER2. Frequent adverse effects include acneiform rash, diarrhea, cramping, and exacerbation of gastroesophageal reflux. When lapatinib is
Inhibitors of Platelet-Derived Growth Factor Receptor (PDGFR)

Signaling by the PDGFR plays a significant part in mesenchymal biology, including stem cell growth, and is involved in oncogenesis through aberrant cancer cell signaling, modulation of the tumor microenvironment, and facilitation of angiogenesis and metastasis. Small-molecule protein kinase inhibitors, including imatinib (see discussion below), have been used in the treatment of patients with GISTs that carry mutations in KIT or PDGFRα (Figure 67–2). The addition of the anti-PDGFR monoclonal antibody olaratumab to doxorubicin treatment (see Chapter 66) improves overall survival of patients with STS (Judson and van der Graaf, 2016).

Olaratumab

**Mechanism of Action**

Olaratumab is a human IgG1 monoclonal antibody that binds to PDGFRα and blocks ligand-mediated receptor activation (Tap et al., 2016).

**Therapeutic Uses**

Olaratumab is indicated, in combination with doxorubicin, for the treatment of adult patients with STS with a histologic subtype for which an anthracycline-containing regimen is appropriate and which is not amenable to curative treatment with radiotherapy or surgery. Recent studies showed that addition of olaratumab to doxorubicin doubled median survival of patients with metastatic STS to 26 months (Judson and van der Graaf, 2016).

**Adverse Effects**

The most common (≥20%) adverse effects of treatment with olaratumab are nausea, fatigue, neutropenia, musculoskeletal pain, inflammation of the mucous membranes (mucositis), alopecia, vomiting, diarrhea, decreased appetite, abdominal pain, neuropathy, and headache. Laboratory abnormalities are lymphopenia, neutropenia, thrombocytopenia, hyperglycemia, elevated aPTT, hypokalemia, and hypophosphatemia. Other adverse effects include infusion-related reactions (low blood pressure, fever, chills, rashes) and embryo-fetal harm.

**Hedgehog Pathway Inhibitors**

The hedgehog signaling pathway was discovered by genetic studies in fruit flies: Mutations resulting in stubby and hairy *Drosophila melanogaster* larvae inspired the naming of the signaling pathway as “hedgehog” or Hh, which is the name of the pathway's polypeptide ligand. Mammals have three hedgehog homologs. The hedgehog pathway controls embryonic cell differentiation in tissues of different species through distinct gradients of hedgehog signaling proteins that are key regulators during development. In adults, hedgehog signaling plays roles in stem cell regulation and tissue regeneration. BCC of the skin is one of several cancers associated with the dysregulation of this pathway.

### Inhibitors of RAFF Kinase: Vemurafenib, Dabrafenib

BRAF belongs to the RAF/mnl family of serine/threonine protein kinases and plays a role in regulating signaling via MAPK (or ERK) (Figure 67–2). In melanoma, MAPK signaling can be constitutively activated through alterations in membrane receptors or through mutations of RAS or BRAF. BRAF mutations confer constitutive activation of the kinase pathway independent of RAS activation. BRAF is mutated in about 55% of melanomas, and 90% of these mutations display a substitution of valine to glutamic acid (V600E) or to lysine (V600K), which results in constitutive protein kinase activation (Vultur and Herlyn, 2013). Approximately 8% of other cancers, colon cancer and NSCLC amongst them, also carry an activating mutation in BRAF. The BRAF inhibitors vemurafenib and dabrafenib are superior to traditional chemotherapy in improving survival in patients with mutant BRAF melanoma and are discussed in the material that follows. In patients with BRAF-mutant lung or colon cancers, only the lung cancer patients show a therapeutic benefit. This finding indicates that colon cancers do not depend on the activated mutant BRAF as a necessary oncogenic driver.
**Vemurafenib**

**Mechanism of Action**

Vemurafenib is an orally bioavailable inhibitor of mutated BRAF (V600E). The name *vemurafenib* is derived from the target, that is, V600E mutated BRAF. Vemurafenib also is effective against the less common BRAF V600K mutation. Melanoma cells lacking these mutations are not inhibited by vemurafenib.

**ADME**

Following oral administration, the elimination half-life for vemurafenib is 7 h.

Vemurafenib is a substrate of CYP3A4 and a substrate and an inhibitor of the Pgp exporter. Vemurafenib can increase concentrations of CYP1A2 substrates. Thus, concomitant use with the centrally acting α₂ adrenergic receptor agonist tizanidine, which has a narrow therapeutic window and is used as a muscle relaxant, should be avoided.

**Therapeutic Uses**

Vemurafenib is FDA approved for the treatment of patients with metastatic melanoma harboring activating BRAF (V600E/K) mutations. It is not indicated for the treatment of patients with melanoma carrying wild-type BRAF.

**Adverse Effects**

The most common adverse effects (30%–60% of patients) are cutaneous events. Arthralgia, fatigue, and nausea are also observed but at a lower frequency. cuSCC and keratoacanthomas that may need surgical removal appear in more than 20% of patients. The median time to the first appearance of these skin lesions is 7 to 8 weeks and is caused by a paradoxical stimulation of wild-type BRAF. Increased photosensitivity reactions can be prevented with sunblock. QT prolongation has been observed, necessitating controlling for risk factors and monitoring ECG and electrolytes.

**Drug Resistance**

Melanoma is one of the most aggressive malignancies, with a high mutation rate that renders these tumors highly heterogeneous and thus prone to the quick development of resistance to drug treatments. After the initial response of melanoma lesions to treatment with vemurafenib, resistant cancer cell subpopulations are selected, typically in less than 6 months. Constitutively active mutant NRAS; downstream mutations in MEK; overexpression of the growth receptor PDGFR-B; activation of parallel pathways such as PI3K/Akt, mTOR, and STAT3 signaling; or stromal cell secretion of HGF can drive this drug resistance (Chapman et al., 2011). Combination treatment with a MEK inhibitor (trametinib, cobimetinib) that acts downstream of BRAF (Figure 67–2) can delay development of resistance to single-agent BRAF inhibitors (Robert et al., 2015).

**Dabrafenib**

**Mechanism of Action**

Dabrafenib is an orally bioavailable, small-molecule inhibitor of mutated forms of BRAF kinases. Dabrafenib can inhibit the proliferation of tumor cells that contain a constitutively active mutated BRAF (V600E). In vitro IC₅₀ values of 0.65, 0.5, and 1.84 nM for the V600E, V600K, and V600D mutations, respectively. At about 5-fold higher concentrations, dabrafenib also inhibits wild-type BRAF and CRAF (IC₅₀ values of 3.2 and 5.0 nM, respectively). Dabrafenib, in combination with trametinib (see discussion that follows), is approved for the treatment of patients with unresectable or metastatic melanoma and NSCLC with BRAF mutations. The drug is not indicated for the treatment of patients with wild-type BRAF melanoma.

**ADME**

The mean terminal half-life of dabrafenib is 8 h after oral administration.

Dabrafenib is metabolized primarily by CYP2C8 and CYP3A4. Patients should be monitored closely for adverse reactions and for loss of efficacy if treated with drugs that induce CYP2C8 and CYP3A4 activity.

**Therapeutic Uses**

Dabrafenib was FDA approved as a single-agent treatment of patients with BRAF V600E mutation-positive advanced melanoma in 2013. Resistance to dabrafenib and other BRAF inhibitors occurs within about 6 months, but a combination with the MEK inhibitor trametinib can delay the development of resistance (see discussion that follows). Thus, the FDA has approved the combination of dabrafenib and trametinib for the treatment of patients with BRAF V600E/K-mutant metastatic melanoma and BRAF V600E-mutant NSCLC.

**Adverse Effects and Drug Interactions**

Adverse effects, in order of decreasing frequency, are hyperkeratosis, headache, pyrexia, arthralgia, papilloma, alopecia, and PPES. An increased incidence of cuSCC is expected in about 10% of patients, with a median time of 2 months to the first diagnosis. About one-third of those patients develop more than one lesion with continued administration of dabrafenib. With the dabrafenib-trametinib combination, the appearance of cuSCC is delayed to a median time of 7 months and occurs in only 3% of patients. Most common adverse reactions (≥20%) for dabrafenib in combination with trametinib are pyrexia, rash, chills, headache, arthralgia, and cough. Cardiomyopathy has also been reported.
and cause resistance to trametinib. Resistance to single-agent trametinib occurs within 6 to 7 months of the initiation of treatment at a rate approaching 50%. As a strategy to overcome resistance, trametinib has been combined with the BRAF inhibitor dabrafenib for the treatment of patients with BRAF V600E/K-mutant metastatic melanoma (Flaherty et al., 2012). This combination has been approved by the FDA.

Cobimetinib
Mechanism of Action; ADME
Cobimetinib is an orally bioavailable, reversible inhibitor of MEK1/2 protein kinase activity with an IC₅₀ of about 4 nM. Its elimination half-life ranges from 1 to 3 days. Cobimetinib is a substrate for CYP3A, and concomitant treatment with inducers or inhibitors of CYP3A will reduce or increase the systemic exposure of patients.

Therapeutic Uses
A combination of cobimetinib and vemurafenib is FDA approved for the treatment of patients with unresectable or metastatic melanoma with a BRAF V600E/K mutation.

Adverse Effects
The most common adverse effects are diarrhea, photosensitivity reaction, nausea, pyrexia, and vomiting. Major hemorrhagic events can occur with cobimetinib; patients should be monitored for signs and symptoms of bleeding. The drug also increases the risk of cardiomyopathy. The safety in patients with decreased LVEF has not been established.

Other MEK Inhibitors
Under development are binimetinib, a MEK inhibitor being studied in patients with NRAS-mutant melanoma, and encorafinib, a BRAF inhibitor being used in combination with binimetinib for patients with BRAF-mutant melanoma.

Inhibitors of Jak1 and Jak2
Janus-associated kinases (Jaks) mediate the signaling of cytokines and growth factors in hematopoiesis and immune function (see, for instance, Figure 35–2). Intraacellular Jak signaling recruits STATs to cytokine membrane receptors (Figure 67–2). After STAT activation and subsequent localization to the nucleus, STATs modulate gene expression. Jak signaling is dysregulated in myelofibrosis and polycythemia vera, which prompted the development of Jak inhibitors. Ruxolitinib is the first drug in this class.

Ruxolitinib
Mechanism of Action; ADME
Ruxolitinib is an orally bioavailable (95%) analogue of ATP that inhibits the protein kinase activities of Jak1 and Jak2 (IC₅₀ value of 3 nM) and exhibits more than 100-fold selectivity for Jak1/2 over Jak3. The half-life of ruxolitinib is about 3 h; its metabolism is mainly via hepatic CYP3A4, with products excreted largely in the urine. In patients with renal or hepatic impairment, a dose reduction is recommended.

Therapeutic Uses
Ruxolitinib is indicated for the treatment of patients with polycythemia vera who have had an inadequate response to hydroxyurea and for the treatment of myelofibrosis.

Adverse Effects and Drug Interactions
The most common adverse reactions, thrombocytopenia and anemia, should be met with a dose reduction or discontinuation of treatment. Infections should be resolved before treatment with ruxolitinib. In a few patients, BCC or squamous cell skin carcinoma may occur, warranting periodic skin examinations during treatment. Strong CYP3A4 inhibitors (e.g., ketoconazole, fluconazole) increase exposure to ruxolitinib and prolong its half-life to 6 h. Due to the adverse hematopoietic effects, postpartum patients should discontinue nursing during drug treatment.

Cyclin-Dependent Kinase (CDK) 4/6 Inhibitors
The CDKs are a family of over 20 serine/threonine protein kinases that regulate intracellular signaling during cell cycle progression (Figure 67–2). Given their pivotal role in cellular proliferation, CDKs are prime targets for development of inhibitors. However, different tissue selectivity and distinct cell cycle–specific activity periods of different CDKs provide a challenge.

CDK4/6 are attractive targets because they control cell cycle progression from the G1 to S phase. Interaction of cyclin D with CDK4/6 enhances phosphorylation of the Rb tumor suppressor protein, inactivating Rb and allowing the transcription of factors that control transition into the S phase. Inhibition of CDK4/6 will inhibit the phosphorylation and inactivation of Rb and cause a G0 arrest in susceptible cells that utilize this pathway, thereby providing the rationale for the use of inhibitors of CDK4/6 (Figure 67–3). This cell cycle checkpoint is frequently compromised in cancers due to cyclin D amplification, loss of Rb function, or loss of negative regulators of CDK4/6, such as p16INK4A, a tumor suppressor named for its molecular mass (it is a small protein of 16 kDa) and its capacity to inhibit CDK4. The class of CDK inhibitory drugs is identified by the syllable ciclib and includes palbociclib, discussed next.

Palbociclib
Mechanism of Action
Palbociclib is an orally bioavailable, small-molecule inhibitor of CDK4 and CDK6, with IC₅₀ values of 11 and 16 nM, respectively, and without inhibitory activity against CDK1, 2, or 5.

Figure 67–3  CDK4 inhibitors: retinoblastoma protein, cyclin-dependent protein kinases, and the regulation of cell cycle progression. In quiescent and differentiated cells (in G₀ or cells arrested in G₁), the Rb protein is active and interacts with a heterodimer of the transcription factor E2F and its dimerization partner DP1, repressing transcription of promoters regulated by E2F. As a cell begins a cycle of division, cyclins activate CDKs that phosphorylate Rb, disrupting the E2F/DP1 complexes and permitting accumulation of active E2F complexes that drive transcription. This cell cycle checkpoint is frequently compromised in cancers due to cyclin D amplification, loss of Rb function, or loss of negative regulators of CDK4/6. Hyperphosphorylation of Rb can occur via mutations in Rb or expression of viral oncoproteins targeting Rb, placing the cell in a state of extensive proliferation, with reduced capability to exit the cell cycle. Inhibition of CDK4/6 can cause G₀ arrest in susceptible cells (Dyson, 2016). CDK inhibitors (in red lettering) are identified by the duylalic suffix “ciclib.”
ADME
The mean plasma elimination $t_{1/2}$ is 29 h. Palbociclib is a substrate and an inhibitor of CYP3A; thus, doses of palbociclib or of substrates of CYP3A4 may need to be reduced when they are given concurrently, with special attention to coadministered agents with narrow therapeutic indices (see the Adverse Effects and Drug Interactions section). The sulfotransferase SULT2A1 also participates in palbociclib metabolism.

Therapeutic Uses
Palbociclib is the first CDK inhibitor approved by the FDA for the treatment of advanced or metastatic breast cancer that is ER positive and HER2 negative. Palbociclib is used in combination with letrozole, an aromatase inhibitor, as initial endocrine-based therapy in postmenopausal women or with the antiestrogen fulvestrant in women with disease progression after endocrine-based therapy. Letrozole and fulvestrant are described in Chapter 68. The inclusion of palbociclib with different endocrine-based treatments almost doubles the progression-free survival of patients (Cristofanilli et al., 2016; Finn et al., 2016).

Adverse Effects and Drug Interactions
The most common adverse effects of palbociclib are neutropenia, leukopenia, infections, stomatitis, fatigue, nausea, anemia, headache, diarrhea, and thrombocytopenia. The most common grades 3 and 4 adverse effects are neutropenia (>60%), leukopenia (>25%), and anemia (>5%). Patients should avoid breastfeeding while taking palbociclib. Letrozole and fulvestrant do not alter the pharmacokinetics of palbociclib.

Patients should avoid concomitant use of strong CYP3A inhibitors (e.g., clarithromycin, indinavir, itraconazole, ketoconazole, lopinavir/ritonavir, nefazodone, nelfinavir, posaconazole, ritonavir, saquinavir, telaprevir, telithromycin, and voriconazole). Coadministration of a strong CYP3A inhibitor (e.g., itraconazole) can markedly increase exposure to palbociclib (by 87% in healthy subjects). Patients should avoid grapefruit or grapefruit juice. If palbociclib coadministration with a strong CYP3A inhibitor cannot be avoided, reduce the dose of palbociclib.

Coadministration of a strong CYP3A inducer will decrease exposure to palbociclib. Thus, avoid concomitant use of phenytoin, rifampin, carbamazepine, enalaprilamide, and St. John’s Wort.

Palbociclib may increase exposure to coadministered CYP3A substrates with narrow therapeutic indices (e.g., midazolam, alfentanil, cyclosporine, dihydroergotamine, ergotamine, everolimus, fentanyl, pimozide, quinidine, sirolimus, and tacrolimus), requiring reduction of palbociclib dose.

Other Drugs That Target CDK4/6
Abemaciclib and ribociclib are CDK4/6 inhibitors with inhibitory profiles similar to that of palbociclib. These inhibitors are currently undergoing clinical trials in patients with breast cancer as well as a variety of other cancers. Ribociclib is FDA-approved for treating breast cancer. The major efficacy and adverse effects of these inhibitors appear to overlap. However, differences in the selectivity for the targeted kinases appear to result in different adverse effect profiles and possibly future uses of these inhibitors (O’Leary et al., 2016).

Bruton Tyrosine Kinase (BTK) Inhibitor
The BTK protein tyrosine kinase plays important roles in the function of B cells. The PH domain of BTK binds PIP3. BTK-PIP3 phosphorylates PLC, which hydrolyzes phosphatidylinositol, thereby activating the IP$_3$-Ca$^{2+}$-PKC pathway in B cells.

Ibrutinib
Mechanism of Action
Ibrutinib is an orally bioavailable, small-molecule inhibitor that inactivates BTK through covalent binding to cys$^{348}$ near the ATP-binding domain.

ADME
Administration with food (vs. on an empty stomach) roughly doubles absorption. The elimination half-life of ibrutinib is 4 to 6 h. It is a substrate of CYP3A; CYP2D6 participates to a minor degree. Metabolites are excreted mainly via the feces; renal excretion is minor. Hepatic impairment is likely to increase ibrutinib exposure. Ibrutinib is not a substrate for Pgp.

Therapeutic Uses
Ibrutinib inhibits malignant B-cell proliferation and is indicated for the treatment of patients with MCL who have received at least one prior therapy, CLL, SLL, and WM.

Adverse Effects and Drug Interactions
The most common adverse effect (≥20%) in patients with B-cell malignancies is neutropenia, pyrexia, thrombocytopenia, hemorrhage, anemia, diarrhea, nausea, musclekeletal pain, rash, and fatigue. The onset of hypertension has been observed within less than a month and up to 2 years after the start of ibrutinib treatment. Thus, blood pressure should be monitored and antihypertensive treatment initiated or modified. Atrial fibrillations are observed in up to 7% of patients; this requires monitoring and treatment. Second primary malignancies occur in up to 16% of patients, most of them nonmelanoma skin cancers.

Strong (e.g.,azole antifungals) and moderate (e.g., diltiazem, erythromycin) CYP inhibitors will increase ibrutinib’s AUC; thus, dose reduction is recommended when using CYP3A inhibitors concomitantly. The reverse is true for strong and moderate CYP inducers (e.g., rifampin, efavirenz), which will decrease ibrutinib exposure.

Ibrutinib is classified pregnancy category D (see Appendix I) and may cause fetal harm. Pregnant patients and those at risk for pregnancy should be apprised of the drug’s hazardous potential.

Acalabrutinib is a second-generation, orally bioavailable, irreversible BTK inhibitor that shows higher selectivity for BTK versus other kinases (e.g., EGFR, ITK) than ibrutinib. Acalabrutinib appears to have less-frequent off-target toxicities. Acalabrutinib received orphan drug designation for the treatment of CLL in the U.S. and for CLL, SLL, MCL, or WM in Europe.

Inhibitors of the BCR-ABL Kinase
A single molecular event, the Philadelphia chromosome translocation t(9;22), leads to expression of ABL and BCR. This fusion generates a constitutively active protein kinase, BCR-ABL, resulting in continuous and uncontrollable cell division. BCR-ABL drives the malignant phenotype of CML (Figure 67–2).

HISTORY BCR-ABL Kinase Inhibitors
Imatinib mesylate, originally named “sti 571” (signal transduction inhibitor 571), was the first protein kinase inhibitor designed to target a driver mutation in a cancer and to receive FDA approval. It was approved in 2001 under the name Gleevec and is now designated as an essential drug by the World Health Organization (WHO). Imatinib targets the BCR-ABL tyrosine kinase fusion protein that drives CML. Imatinib-resistant ABL mutations were uncovered in 2002 and led to the development of next-generation inhibitors dasatinib and nilotinib, which overcome the resistance.

Imatinib and the second-generation inhibitors dasatinib and nilotinib induce clinical and molecular remissions in more than 90% of patients with CML in the chronic phase of disease. Due to its inhibition of other kinases, imatinib is also effective in some other tumors, including GISTs (driven by a c-KIT mutation), hyperesinosophilia syndrome, and dermatofibrosarcoma protuberans (all driven by activating mutations in the PDGFR; see Figure 67–2).

Imatinib, Dasatinib, and Nilotinib
Mechanisms of Action
These are orally bioavailable, small-molecule kinase inhibitors. Imatinib was identified through high-throughput screening against the BCR-ABL kinase. Dasatinib, a second-generation BCR-ABL inhibitor, also inhibits
the Src kinase, and unlike imatinib, it binds both the open (active) and closed (inactive) configurations of the BCR-ABL kinase. Nilotinib was designed to have increased potency and specificity compared to imatinib. Its structure overcomes mutations that cause imatinib resistance. Imatinib and nilotinib bind to a subset of the kinase domain that fixes the enzyme in a closed or nonfunctional state, in which the protein is unable to bind its substrate/phosphate donor, ATP. These three BCR-ABL kinase inhibitors differ in their inhibitory potencies, binding specificities, and susceptibility to resistance mutations in the target enzyme. Dasatinib (IC_{50} = 1 nM) and nilotinib (IC_{50} = 20 nM) inhibit BCR-ABL kinase more potently than imatinib (IC_{50} = 100 nM).

Mechanisms of Resistance

Resistance to these TKIs arises from point mutations in three separate segments of the kinase domain. The contact points between imatinib and the enzyme become sites of mutations in drug-resistant leukemic cells; these mutations prevent tight binding of the drug and lock the enzyme in its open configuration, in which it has access to substrate and is enzymatically active. Imatinib retains inhibitory activity in the presence of most point mutations that confer resistance to imatinib. Other mutations affect the phosphate-binding region and the “activation loop” of the domain with varying degrees of associated resistance. Some mutations, such as those at amino acids 351 and 355, confer low levels of resistance to imatinib, whereas others, such as those at amino acids 315 and 316, confer high levels of resistance.

Other mutations affect the kinase domain. The contact points between imatinib and the enzyme become sites of mutations in drug-resistant leukemic cells; these mutations prevent tight binding of the drug and lock the enzyme in its open configuration, in which it has access to substrate and is enzymatically active. Imatinib retains inhibitory activity in the presence of most point mutations that confer resistance to imatinib. Other mutations affect the phosphate-binding region and the “activation loop” of the domain with varying degrees of associated resistance. Some mutations, such as those at amino acids 351 and 355, confer low levels of resistance to imatinib, whereas others, such as those at amino acids 315 and 316, confer high levels of resistance.

Molecular studies have detected cells with resistance-mediated kinase mutations prior to initiation of therapy, particularly in patients with Ph+ ALL or CML in blast crisis. This finding indicates that drug-resistant cells arise through spontaneous mutation and expand under the selective pressure of drug exposure. Mechanisms other than BCR-ABL kinase mutations play a minor role in resistance to imatinib. Amplification of the wild-type kinase gene, leading to overexpression of the enzyme, has been identified in tumor samples from patients resistant to treatment. The MDR gene confers resistance experimentally but has not been implicated in clinical resistance. Ph clones lacking the BCR-ABL translocation and displaying the karyotype of myelodysplastic cells may emerge in patients receiving imatinib for CML; these may progress to MDS and AML. Their origin is unclear.

A comparison amongst secondary mutations in the EGFR, ABL, and KIT kinases following treatment with BCR-ABL kinase inhibitors shows striking differences: The T790M gatekeeper mutation in the EGFR (Figure 67–1) accounts for about 90% of secondary mutations. In contrast, secondary resistance mutations in ABL or KIT after treatment of CML or GIST with imatinib are found across the kinase domain and rarely at the analogous gatekeeper residue in ABL (T790) or in KIT (T758).

ADME

Imatinib is well absorbed after oral administration and reaches maximal plasma concentrations within 2–4 h. The elimination t_{1/2} of imatinib and its major active metabolite, the N-desmethyl derivative, are about 18 and 40 h, respectively. Food does not change the pharmacokinetic profile. Does of more than 300 mg/d achieve trough levels of 1 μM, which correspond to in vitro levels required to kill BCR-ABL-expressing cells. In the treatment of GISTs, higher doses may improve response rates. CYP3A4 is the major metabolizer of imatinib; thus, drugs that induce or interact with CYP3A4 can alter the pharmacokinetics of imatinib. Co-administration of imatinib and rifampin, an inducer of CYP3A4, lowers the plasma imatinib AUC by 70%. Imatinib, as a competitive CYP3A4 substrate, inhibits the metabolism of simvastatin and increases its plasma AUC by 3.5-fold.

Dasatinib. Oral dasatinib is well absorbed; its bioavailability is significantly reduced at neutral gastric pH (i.e., after antacids and H₂ blockers) but is unaffected by food. The plasma t_{1/2} of dasatinib is 3–5 h. Dasatinib exhibits dose-proportional increases in AUC, and its clearance is constant over the dose range of 15–240 mg/d. Dasatinib is metabolized primarily by CYP3A4, with minor contributions by FMO3 and UGT. The major metabolite is equipotent to the parent drug but represents only 5% of the AUC. Plasma concentrations of dasatinib are affected by inducers and inhibitors of CYP3A4 in a similar fashion to imatinib.

Nilotinib. Approximately 30% of an oral dose of nilotinib is absorbed after administration, with peak concentrations in plasma 3 h after dosing. Unlike the other BCR-ABL inhibitors, nilotinib’s bioavailability increases significantly in the presence of food. The drug has a plasma t_{1/2} about 17 h, and plasma concentrations reach a steady state only after 8 days of daily dosing. Nilotinib is metabolized by CYP3A4, with predictable alteration by inducers, inhibitors, and competitors of CYP3A4. Nilotinib is a substrate and an inhibitor of Pgp.

Therapeutic Uses

These protein TKIs have efficacy in diseases in which ABL, KIT, or PDGFR have dominant roles in driving tumor growth, reflecting the presence of a mutation that results in constitutive activation of the kinase. Imatinib shows therapeutic benefits in patients with chronic-phase CML (BCR-ABL) or GIST and a subset of patients with mucosal or acral lentiginous melanoma (KIT mutation positive), chronic myelomonocytic leukemia (EVT6-PDGFR translocation), hypereosinophilic syndrome (FIP1L1-PDGF), and dermatofibrosarcoma protuberans (constitutive production of the ligand for PDGF). It is the agent of choice for patients with metastatic GIST and is used as adjuvant therapy of c-KIT–positive GIST. Dasatinib is approved for patients with newly diagnosed CML with resistance to or intolerance of imatinib in both chronic and advanced phases of disease and for use combined with cytotoxic chemotherapy in patients with Ph+ ALL who are resistant or intolerant to prior therapies.

Adverse Effects

Imatinib, dasatinib, and nilotinib cause GI symptoms (diarrhea, nausea, and vomiting) that are usually readily controlled. All three drugs promote fluid retention, edema, and periorbital swelling. Myelosuppression occurs infrequently but may require transfusion support and dose reduction or discontinuation of the drug. These drugs can be associated with hepatoxicity. Dasatinib may cause pleural effusions and pulmonary hypertensin in a small subset of patients. Nilotinib and dasatinib may prolong the QT interval; nilotinib has been associated with cardiac and vascular events, including ischemia. Most nonhematological adverse reactions are self-limited and respond to dose adjustments. After the adverse reactions have resolved, the drug may be reintiated and titrated back to effective doses.

Bosutinib

Bosutinib is another second-generation, orally bioavailable BCR-ABL kinase inhibitor (IC_{50} = 1.2 nM). Bosutinib also inhibits activity of Src (IC_{50} = 1 nM) and other members of the Src family. It is FDA approved for the treatment of patients with chronic, accelerated, or blast-phase Ph+ CML with resistance or intolerance to prior therapy. The most common adverse reactions (incidence greater than 20%) are diarrhea, nausea, thrombocytopenia, vomiting, abdominal pain, rash, anemia, pyrexia, and fatigue.

Ponatinib

Ponatinib is a third-generation BCR-ABL kinase inhibitor. Imatinib (first generation) lacks efficacy for the more advanced disease phases, and cells with mutations in the BCR-ABL tyrosine kinase domain are resistant. Second-generation inhibitors (nilotinib, dasatinib, bosutinib) were developed to address these weaknesses, although they do not inhibit the T315I mutant of BCR-ABL that is found in 15%–20% of patients with CML.

Mechanism of Action

Ponatinib is a third-generation, orally bioavailable kinase inhibitor that is active against the T315I mutant BCR-ABL and also is effective toward all other known BCR-ABL1 kinase mutants. IC_{50} values (nM) for different kinases are as follows: ABL, 0.37; PDGFR, 1.1; VEGFR2, 1.5; FGFR1, 2.2; and Src, 5.4.

ADME

Peak ponatinib concentrations are observed within 6 h and are unaffected by food or fasting. Drug solubility is pH dependent, with higher pH resulting in decreased solubility. Accordingly, drugs that affect gastric pH (such
as H₂S, antagonists, antacids, and PPIs) may significantly alter ponatinib bioavailability. Ponatinib is highly (99%) bound to plasma proteins and is a weak substrate for Pgp and ABCG2 transporters. Metabolism is primarily via CYP3A4 and to lesser extents by CYPs 2C8, 2D6, and 3A511; esterases; and amidases. Coadministration of CYP3A inhibitors significantly increases ponatinib concentrations. The t½ of ponatinib is about 24 h. Unmetabolized ponatinib is primarily excreted in the feces (87%), with a small portion (5%) in the urine.

Therapeutic Uses
Ponatinib is approved for resistant CML and Ph⁺ ALL. Clinical cytogenetics measurements are a key tool for monitoring the response to therapy, reported as the percentage of Ph⁺ karyotypes in 20 bone marrow metaphases (major cytogenetic response; MCyR). Ponatinib produces an overall major molecular response (MMR) rate of 42%. The most common adverse reactions are GI toxicity including nausea, diarrhea, and vomiting as well as hepatic, respiratory, and ocular toxicity and neuropathy. Also observed are QT prolongation and bradycardia.

Inhibitors of Anaplastic Lymphoma Kinase (ALK)
ALK is a membrane monospan with an extracellular domain and an intracellular protein tyr kinase domain (Figure 67–2). The importance of this protein kinase in human cancers is the capacity of the ALK gene to form fusion genes that become oncogenic drivers. A 2.5 chromosomal translocation yields an oncogenic fusion gene in which a 3′ portion of ALK (chromosome 2) contributes coding for the catalytic domain and is joined to a 5′ region of the NPM gene. The extracellular and transmembrane sequences of ALK are absent in the ALK-NPM fusion gene, which is the oncogenic driver of malignant progression in anaplastic large cell lymphoma (ALCL). A similar translocation of the ALK kinase and fusion with EML4 creates the oncogenic driver in a subset of NSCLC (Martelli et al., 2010), as shown in Figure 67–2. ALK also fuses with numerous additional 5′ partners (Roskoski, 2017). Alectinib, crizotinib, and ceritinib are small-molecule inhibitors of ALK kinase that are used in the treatment of ALK translocation-positive cancers.

Crizotinib
**Mechanism of Action**
Crizotinib is an orally bioavailable inhibitor of receptor tyrosine kinases that include HGF/cMET, ALK, and ROS1. IC₅₀ values are 11 nM and 24 nM for HGF/cMet and ALK, respectively.

**ADME**
Crizotinib is predominantly metabolized by CYP3A4/5 and shows a terminal half-life of 42 h. The typical dose of 250 mg twice daily is reduced to once daily in patients with severe renal impairment and a creatinine clearance below 30 mL/min.

**Therapeutic Uses**
Crizotinib is approved for the treatment of patients with locally advanced or metastatic NSCLC harboring ALK or ROS1 gene rearrangements (Figure 67–2) (Thomas et al., 2015). The ROS1 gene product is a receptor tyr protein kinase that is structurally similar to ALK. ROS1 also participates in gene translocations and the formation of oncogenic fusion genes that have a 1% incidence in lung cancers.

**Adverse Effects**
The most common adverse reactions are GI toxicity including nausea, diarrhea, and vomiting as well as hepatic, respiratory, and ocular toxicity and neuropathy. Also observed are QT prolongation and bradycardia.

Alectinib
**Mechanism of Action**
Alectinib is an orally bioavailable inhibitor of ALK kinase activity with an IC₅₀ of 1.9 nM. Alectinib shows a higher selectivity for ALK than crizotinib and is active against mutant forms of ALK that are found in tumors resistant to crizotinib.

**ADME**
Alectinib has an elimination half-life of 33 h and is metabolized by CYP3A4. Co-administration of alectinib with CYP3A inhibitors or inducers will alter plasma concentrations.

**Therapeutic Uses**
Alectinib is approved for the treatment of patients with advanced or recurrent NSCLC harboring the ALK fusion gene (ALK+). Patients with ALK+ NSCLC who have progressed on treatment with crizotinib or are intolerant to crizotinib also qualify.

**Adverse Effects**
The most common adverse effects are fatigue, constipation, edema, and myalgia. Pneumonitis, GI toxicity, hepatotoxicity, bradycardia, and prolonged QT intervals are also observed (Katayama et al., 2015).

Ceritinib
Ceritinib is an orally bioavailable ALK inhibitor approved for the treatment of ALK+ metastatic NSCLC that is unresponsive to crizotinib. Common adverse effects are GI toxicity and hepatotoxicity. Bradycardia and prolonged QT intervals also occur.

Inhibitors of the PI3K/Akt/mTOR Pathway
**Background**
Activation of PI3K and the consequent activation of signaling events through protein kinase B (Akt) and the mechanistic or mTOR pathway are important in cell growth and survival and in regulation of cell metabolism (Figures 67–2 and 67–5). Excessive signaling through the PI3K pathway is a frequent aberration in many human cancers; thus, this pathway is an attractive target in cancer therapy. There are three classes of PI3Ks: The class I PI3K enzymes are the most important in cancer. These isoforms are activated by receptor protein tyrosine kinases and GPCRs. The PI3K enzymes are heterodimers of a p85 regulatory subunit and a p110 catalytic subunit. The p110 subunit exists in four identified isoforms: α, β, γ, and δ. The α and β isoforms are ubiquitously expressed, whereas the γ and δ isoforms are predominantly expressed in cells of hematopoietic origin. The different catalytic subunits have distinct roles in normal and malignant B-cell function. PI3Ka, containing the 110α, catalytic subunit, is the most frequently mutated PI3K in human cancer (Fruman and Rommel, 2014). In B-cell malignancies, the PI3Kδ isoform is frequently activated. A recently approved PI3Kδ inhibitor, idelalisib, is described in the next section. Currently, the mTORC1 inhibitors sirolimus (rapamycin), everolimus, and temsirolimus are approved for clinical use in different cancers and are described in the material that follows. Ongoing clinical trials are evaluating the safety and efficacy of pan-PI3K inhibitors, inhibitors of the PI3Kα isoform, as well as inhibitors of AKT, PI3K/mTOR, and TORC1/TORC2.

**PI3Kδ Inhibitor: Idelalisib**
The PI3Kδ isoform is constitutively activated in many B-cell malignancies, and inhibition of this pathway can promote apoptosis in these cancer cells.

**Mechanism of Action**
Idelalisib is an orally bioavailable inhibitor of the PI3Kδ isoform with an IC₅₀ of about 8 nM. It is 40- to 300-fold more selective for the PI3Kδ isoform than for the other isoforms.

**ADME**
Food does not affect absorption of idelalisib. The drug is metabolized by aldehyde oxidase, CYP3A, and UGT1A4, yielding an elimination half-life of 1215 hours.
of 8.2 h. Idelalisib inhibits CYP3A and is a substrate of Pgp and of the efflux transporter BCRP/ABCG2 in vitro. Idelalisib increases plasma levels of midazolam (a CYP3A substrate) but does not affect plasma levels of digoxin (a Pgp substrate) or rosuvastatin (an OATP1B1/B3 substrate).

Patients receiving strong CYP inhibitors may be at increased risk for idelalisib toxicity. Hepatic impairment increases systemic exposure, putting patients at risk for toxicity.

**Clinical Use**

Idelalisib is approved for the treatment of relapsed or refractory B-cell malignancies in patients who have received at least two prior systemic therapies. This includes CLL in combination with rituximab, FL, and SLL. Idelalisib is not indicated and is not recommended for first-line treatment.

**Adverse Effects**

Idelalisib may cause serious and sometimes-fatal adverse effects, including liver toxicity, diarrhea, colitis, pneumonitis, intestinal perforations, and skin toxicity. Patients taking idelalisib should avoid other hepatotoxic drugs. Other common side effects include fever, chills, cough, pneumonia, fatigue, nausea, abdominal pain, rash, hyperglycemia, and elevated levels of triglycerides and liver enzymes. Idelalisib may cause embryo-fetal toxicity. Breastfeeding during therapy is contraindicated because of the potential for adverse reactions in nursing infants.

**mTOR Inhibitors: Rapamycin Analogues**

Rapamycin (sirolimus) is a product from a strain of Streptomyces found on the Rapa Nui Easter Island. It inhibits a serine/threonine protein kinase in mammalian cells named mTOR. The PI3K/PKB(Akt)/mTOR pathway responds to a variety of signals from growth factors. The activation of the PI3K pathway is opposed by the phosphatase activity of the tumor suppressor, PTEN (Figure 67–2). Activating mutations and amplification of genes in the receptor-PI3K pathway, and loss of function alterations in PTEN, occur frequently in cancer cells, with the result that PI3K signaling is exaggerated, and cells exhibit enhanced survival. Rapamycin (sirolimus) and its congeners, the so-called rapalogs temsirolimus and everolimus, are first-line drugs in posttransplant immunosuppression (see Figure 35–2) and are used in coronary artery stents to prevent fibrotic growth. Rapalogs have been approved for the treatment of patients with renal cancer; NETs of the pancreas; NETs of GI tract or lung origin; anti–hormone refractory; hormone receptor–positive breast cancer; and for patients with TSC-related tumors.

**Mechanism of Action**

The rapamicyns inhibit an enzyme complex, mTORC1, which occupies a downstream position in the PI3K pathway (Figure 67–4). mTOR forms the mTORC1 complex with a member of the FK506-binding protein family, FKBP12. The antitumor actions of the rapamicyns result from their binding to FKBP12 and preventing activation of mTOR, as detailed in Figure 67–4 and its legend.

**ADME**

For renal cell cancer, temsirolimus is given in weekly intravenous doses of 25 mg; temsirolimus is metabolized by CYP3A4; the parent drug has a plasma t1/2 of 30 h, but its primary active metabolite, sirolimus (rapamycin), has a t1/2 of 53 h. Because sirolimus has equivalent activity as an inhibitor of mTORC1 and has a greater AUC, sirolimus is likely the more important contributor to antitumor action in patients. The concomitant use of strong CYP3A4 inhibitors or inducers should thus be avoided. Grapefruit juice may also increase plasma concentrations of the active metabolite sirolimus and should be avoided.

Everolimus is administered orally in doses of 10 mg/d and is metabolized by CYP3A4. Everolimus has a plasma t1/2 of 30 h; on a weekly schedule at doses of 20 mg, it maintains inhibition of mTORC1 for 7 days in white blood cells. Both drugs are susceptible to interactions with other agents that affect CYP3A4 activity. For everolimus, the dose should be reduced for patients with moderate hepatic impairment; guidelines for dose reduction of temsirolimus in such patients have not been established. The drugs' pharmacokinetics do not depend on renal function, and hemodialysis does not hasten temsirolimus clearance.

**Therapeutic Uses**

Temsirolimus and everolimus are approved for treatment of patients with advanced renal cancer. Temsirolimus prolongs survival and delays disease progression in patients with advanced and poor- or intermediate-risk renal cancer, as compared to standard IFN-a treatment. Everolimus, as compared to placebo, prolongs survival in patients who had failed initial treatment with antiangiogenic drugs. mTOR inhibitors also have antitumor activity against MCLs. Everolimus is approved for the treatment of postmenopausal women with advanced hormone receptor–positive, HER2–negative breast cancer in combination with exemestane after failure of treatment with letrozole or anastrozole. Other indications are PNET and progressive, well-differentiated, nonfunctional NETs of GI or lung origin as well as TSC-related tumors.

**Adverse Effects; Resistance**

The rapamycin analogues cause similar patterns of adverse effects: a mild maculopapular rash, mucositis, anemia, and fatigue (30%–50%). A few patients will develop leukopenia or thrombocytopenia, effects that are reversed if therapy is discontinued. Less common side effects include hyperglycemia, hypertriglyceridemia, and, rarely, pulmonary infiltrates and interstitial lung disease. Pulmonary infiltrates emerge in 8% of patients receiving everolimus and in a smaller percentage of those treated with temsirolimus. If symptoms such as cough or shortness of breath develop or radiological changes progress, the drug should be discontinued. Prednisone may hasten the resolution of radiological changes and symptoms.

Resistance to mTOR inhibitors is incompletely understood but may arise through the action of a second mTOR complex, mTORC2, which is unaffected by rapamycins and which can upregulate Akt activity (Figure 67–4).

**Multikinase Inhibitors**

Selectivity of small-molecule protein kinase inhibitors for their targets is dependent on the similarity of the targeted site with sites in other kinases and the chemical composition of the inhibitor. Most inhibitors interact with the ATP-binding site of their target that is relatively conserved within a kinase family; thus, such inhibitors have only relative specificity and will cross-react at higher concentrations with closely related kinases. Nonetheless, inhibition of distantly related kinases is possible. The selectivity of inhibitors for a range of targets in the kinase is determined experimentally using assays with recombinant kinase proteins and in vivo using intact cells that express the kinases (Elkins et al., 2015). Inhibitors that target multiple kinase families within the clinically used dose range can be therapeutically efficacious and are discussed in the material that follows. In using drugs directed toward protein kinases, remember that the specificity of these agents is not absolute and that the inhibited kinases often serve important “normal” functions in the cell in addition to the pathologic functions being targeted.

**Cabozantinib**

**Mechanism of Action**

Cabozantinib is an orally bioavailable, small-molecule inhibitor of several tyrosine kinases; as ranked by the IC50 values (in nM) from in vitro assays, these protein kinases are VEGFR2, 0.035; MET, 1.3; RET, 4; KIT, 4.6; VEGFR, 3.6; AXL, 7; FLT3, 11.3; VEGFR1, 12; and TIE2, 14.3. These receptor tyrosine kinases control normal cellular function and pathologic processes that include maintenance of the tumor microenvironment, tumor angiogenesis, and metastatic spread.

**ADME**

The elimination half-life of cabozantinib is about 99 h. Cabozantinib is a substrate of CYP3A4; thus, the dose of cabozantinib should be reduced in patients with mild-to-moderate hepatic impairment as well as for concurrent administration of CYP3A4 inhibitors. Conversely, strong inducers of CYP3A4 will reduce exposure to the drug and necessitate increased dosage of cabomatinib unless the CYP inducers can be avoided.
**Figure 67–4 Caveat mTOR: effect of rapamycin on growth factor signaling.** The PI3K–mTOR pathway responds to extracellular signals, the metabolic and nutrient status, and the energy charge of the cell, transmitting signals downstream that drive maintenance and proliferation (Hall, 2016). mTOR activity appears to contribute to resistance to many targeted cancer therapies (Guri and Hall, 2016), and dysregulation of the pathway is implicated in diabetes, cancer, and other pathologies (Dibble and Cantley, 2015). In this simplified version of the PI3K–mTOR pathway, the green shapes show the action pathway from membrane receptor to the mTOR multiprotein complex, mTORC1. Substrates of the mTOR ser/thr protein kinase activity and integrated responses are shown in blue across the bottom of the figure. Red T bars represent inhibitory influence. Signaling through the pathway is initiated by agonist activation of membrane receptors such as IGF1R and stimulation of their tyr kinase activities, leading to activation of PI3K, which phosphorylates the inositol ring of the PIP2 in the membrane to produce PIP3. PIP3 recruits to the membrane several proteins containing PH domains, including PKD1 and Akt. Akt, also known as PKB, phosphorylates TSC-2 (a subunit of TSC) at multiple sites. TSC is a GAP for Rheb. Phosphorylation of TSC inhibits its GAP activity, thereby reducing the GTPase activity of Rheb and increasing the fraction of Rheb in the GTP-ligated state. Rheb, in its GTP-ligated configuration, activates mTORC1. TSC phosphorylation and PIP3 phosphorylation can be reversed by the phosphatase PTEN. mTORC1 phosphorylates substrates that mediate downstream effects; amongst them are the following:

- HIF-1, leading to increased angiogenesis. HIF-1 is overexpressed in many cancers.
- S6K1, enhancing protein synthesis. Diphospho S6K1 exists in a complex with elf3; phosphorylation by mTOR dissociates the complex, freeing S6K1 to phosphorylate its targets that promote translation.
- 4EBP (euarkytic initiation factor 4e binding protein), thereby enhancing translation. 4EBP is a repressor of mRNA translation via its inhibitory interaction with euarkytic initiation factor 4e (elf4e). The phosphorylation of 4EBP by mTOR reduces the capacity of 4EBP to inhibit elf4e and slow translation.
- ULK1 (unc-51 like autophagy activating kinase 1), whose phosphorylation reduces autophagic activity. mTOR activity prevents ULK1 activation by disrupting its interaction with AMP-activated protein kinase (AMPK), a key promoter of autophagy.

Rapamycin (sirolimus) and the “rapalog” everolimus and temsirolimus inhibit mTOR by associating with the intracellular protein FKB12. The FKB12-rapalog complex binds directly to mTOR and inhibits its functions in the multiprotein complex mTORC1. mTORC2 remains relatively unaffected by mTORC1 inhibitors and can respond by upregulating Akt activity.
Cancer cells secrete angiogenic factors that induce the formation of new blood vessels and guarantee the flow of nutrients to the tumor cells to permit growth and metastasis. Many tumor types overexpress these angiogenic factors, turning on an “angiogenic switch” whereby the tumor cells adopt an invasive phenotype favoring proliferation of endothelial cells and neovascularization. In 1971, Judah Folkman hypothesized that the growth of solid tumors was dependent on angiogenesis and that blockade of the effects of putative angiogenic factors would be a good treatment modality for human cancers (Folkman, 1971). Folkman’s hypothesis proved to be correct and led to the characterization of a number of secreted angiogenic factors, including VEGF, FGF, TGF-β, and PDGF. Furthermore, inhibitors of these angiogenic factors have, indeed, become useful therapeutic agents against certain cancers. VEGF is a major driver of angiogenesis, and inhibitors of VEGF signaling comprise an important class of antitumor agents.

### Inhibition VEGF and the VEGFR Pathway

Vascular endothelial growth factor initiates endothelial cell proliferation and vascular permeability when it binds to a member of the VEGFR family, a group of highly homologous receptors with intracellular tyrosine kinase domains; these receptors include VEGFR1 (FLT1), VEGFR2 (KDR), and VEGFR3 (FLT4) (Figure 67–2). The binding of VEGF to its receptors activates the intracellular VEGFR tyrosine kinase activity and initiates mitogenic and antiapoptotic signaling pathways (Nagy et al., 2007). Antibodies targeting VEGF, such as bevacizumab, sterically hinder the interaction of VEGF with its receptor. Aflibercept acts as a VEGF trap; it is a recombinant molecule that uses the VEGFR1-binding domain to sequester VEGF, basically acting as a “soluble decoy receptor” for VEGF. Several small-molecule drugs that inhibit the protein tyr kinase function of VEGFR (pazopanib, sorafenib, sunitinib, and axitinib) as well as monoclonal antibodies that target the receptor (ramucirumab) have been approved for clinical use. The inhibition of endothelial function by these different approaches results in a similar spectrum of adverse effects.

### Bevacizumab

**Mechanism of Action**

Bevacizumab is a humanized monoclonal IgG1 antibody that binds to VEGF; the antibody contains the antigen-recognition domain of a murine antibody inserted into a human IgG1. Bevacizumab prevents the interaction of VEGF with its receptors on the surface of endothelial cells and inhibits receptor signaling that normally increases vascular permeability and angiogenesis. Bevacizumab delays progression of renal cell cancer and, in combination with cytotoxic chemotherapy, is approved in the treatment of patients with mCRC as well as NSCLC and glioblastoma.

**Therapeutic Use in Cancer**

Bevacizumab is indicated as treatment of various cancers, frequently in combination with other drugs. In metastatic colon cancer, bevacizumab combined with FOLFIRI or FOLFIRI increases patient survival by about 5 months (Hurwitz et al., 2004). In NSCLC, a combination of bevacizumab with carboplatin and paclitaxel increases survival by about 2 months. Also approved are combinations of bevacizumab with cytotoxic chemotherapy in patients with cervical or ovarian cancer and a combination with IFN-α for the treatment of metastatic RCC. For glioblastoma, bevacizumab is approved as a single agent following prior therapy.

### Other Therapeutic Uses: Wet Macular Degeneration

Vascular endothelial growth factor is an important mediator of pathologic vascular permeability. Intravitreous administration of anti-VEGF targeted therapy has become a standard treatment of wet macular degeneration (see also Chapter 69). Bevacizumab and a modified fragment of bevacizumab, ranibizumab, are used. Ranibizumab is derived from the bevacizumab IgG1 by deletion of the Fc domain and changes in six amino acids in the antigen-recognition domain to increase affinity for VEGF.

Because these drugs are administered by injection into the vitreous cavity of the eye, few systemic adverse effects are observed. A direct
comparison of intravitreous bevacizumab, ranibizumab, and aflibercept (the VEGF trap protein; see discussion that follows) in patients with diabetic macular edema showed that all three treatments improved vision, although aflibercept appeared more effective in patients with worse baseline levels of visual impairment (Wells et al., 2015).

Adverse Effects. Bevacizumab causes a wide range of serious class-related adverse effects that include hypertension, GI perforation, thromboembolic events, and hemorrhage. A major concern is the potential for vessel injury and bleeding in patients with lung cancer. Bevacizumab is contraindicated for patients with a history of hemoptysis, brain metastasis, or a bleeding diathesis. In appropriately selected patients, the predicted rate of life-threatening pulmonary hemorrhage is less than 2%, and for arterial thromboembolism (stroke; myocardial infarction) observed during treatments that include bevacizumab the predicted rate is less than 4%.

Other adverse effects characteristic of drugs that target the VEGF pathway include hypertension and proteinuria. A majority of patients require antihypertensive therapy, particularly those receiving higher doses and more prolonged treatment. Bevacizumab can be associated with congestive heart failure, probably secondary to hypertension, and with reversible posterior leukoencephalopathy in patients with poorly controlled hypertension. GI perforation, a potentially life-threatening complication, has been observed in up to 11% of patients with ovarian cancer. In patients with colon cancer, colonic perforation occurs infrequently during bevacizumab treatment but increases in frequency in patients with intact primary colonic tumors, peritoneal carcinomatosis, peptic ulcer disease, chemotherapy-associated colitis, diverticulitis, or prior abdominal radiation treatment. Perforation of the colon occurs in less than 1% of patients. Following colon cancer surgery, patients on bevacizumab have a higher rate (13% vs. 3.4%) of serious wound-healing complications. Because of the long t½ of bevacizumab, elective surgery should be delayed for at least 4 weeks from the last dose of antibody, and treatment should not be resumed for at least 4 weeks after surgery.

Ramucirumab

Mechanism of Action
Ramucirumab is a human IgG1 monoclonal antibody that binds to VEGFR2, blocking the binding of VEGF ligands and thereby inhibiting ligand-induced activity in endothelial cells.

ADME
Ramucirumab is administered intravenously every 2 to 3 weeks. Its mean half-life is 14 days.

Therapeutic Uses
Ramucirumab is used in combination with chemotherapy for the treatment of patients with mCRC with disease progression on or after prior therapy; as a single agent or in combination with paclitaxel for treatment of patients with advanced gastric adenocarcinoma, peritoneal carcinomatosis, peptic ulcer disease, chemotheraphy-associated colitis, diverticulitis, or prior abdominal radiation treatment. Perforation of the colon occurs in less than 1% of patients. Following colon cancer surgery, patients on bevacizumab have a higher rate (13% vs. 3.4%) of serious wound-healing complications. Because of the long t½ of bevacizumab, elective surgery should be delayed for at least 4 weeks from the last dose of antibody, and treatment should not be resumed for at least 4 weeks after surgery.

Adverse Effects
The most common adverse effects are hypertension and diarrhea. Other severe adverse effects overlap with those of bevacizumab (anti-VEGF; see previous discussion): increased risk of hemorrhage, GI perforation, and impaired wound healing.

Aflibercept

Mechanism of Action
Ziv-aflibercept acts as a trap for VEGFR ligands. It is a recombinant fusion protein that contains the extracellular VEGF-binding domain of human VEGFR1/2 fused to the Fc portion of human IgG1. Ziv-aflibercept acts as a soluble receptor that binds to human VEGFR ligands with high affinity (Kₜ₀ of 0.3 to 40 pM), reducing their plasma concentrations to levels that are too low for significant activation of their cognate receptors.

Adverse Effects. Ziv-aflibercept is administered by intravenous infusion over 1 h every 2 weeks.

Therapeutic Uses
In combination with FOLFIRI, aflibercept is indicated for patients with mCRC that is resistant to or has progressed following an oxaliplatin-containing regimen.

Antiangiogenic Small-Molecule Kinase Inhibitors

Sunitinib

Mechanism of Action
Sunitinib is a small-molecule, orally bioavailable inhibitor of multiple kinases, including VEGFR2.

ADME
The typical treatment cycle of sunitinib is 4 weeks on treatment followed by 2 weeks off. The dosage and schedule of sunitinib can be decreased in patients with adverse effects. More recently, a 2-week on/1-week off schedule has proven to be better tolerated and as effective as the original treatment schedule. Sunitinib is metabolized by CYP3A4 to produce an active metabolite, SU12662, the t½ of which is 80–110 h; steady-state levels of the metabolite are reached after about 2 weeks of repeated administration of the parent drug. Further metabolism results in the formation of inactive products. The pharmacokinetics of sunitinib are not affected by food intake.

Therapeutic Uses
Sunitinib has activity in metastatic renal cell cancer, producing a higher response rate and a longer progression-free survival than seen with IFN or bevacizumab. Sunitinib is also approved for the treatment of pancreatic NETs and of GIST in patients who have developed resistance to imatinib as a consequence of c-KIT mutations. Specific c-KIT mutations correlate with the degree of response to sunitinib (e.g., patients with c-KIT exon 9 mutations have a response rate of 37%; patients with c-KIT exon 11 mutations have a 5% response rate).

Adverse Effects
The main adverse effects of sunitinib are shared by all antiangiogenic inhibitors: bleeding, hypertension, proteinuria, and, uncommonly, arterial thromboembolic events and intestinal perforation. However, because sunitinib is a multitargeted TKI, it has a broader adverse effect profile than bevacizumab. Fatigue affects 50%–70% of patients and may be disabling. Hypothyroidism occurs in 40%–60% of patients. Bone marrow suppression and diarrhea also are common side effects; severe neutropenia (neutrophils < 1000/mL) develops in 10% of patients. Less common side effects include hepatotoxicity, congestive heart failure and PPES. It is essential to check blood counts and thyroid function at regular intervals. Periodic echocardiograms also are recommended.

Sorafenib

Mechanism of Action and Therapeutic Use
Sorafenib, like sunitinib, is an orally bioavailable inhibitor of multiple protein kinases. Sorafenib is the only drug currently approved for treatment of patients with hepatocellular carcinoma. Sorafenib also is approved in patients with metastatic renal cell cancer, but sunitinib and pazopanib are generally preferred first-line therapies (see previous discussion and below).

ADME
Sorafenib has activity in metastatic renal cell cancer, producing a higher response rate and a longer progression-free survival than seen with IFN or bevacizumab. Sunitinib is also approved for the treatment of pancreatic NETs and of GIST in patients who have developed resistance to imatinib as a consequence of c-KIT mutations. Specific c-KIT mutations correlate with the degree of response to sunitinib (e.g., patients with c-KIT exon 9 mutations have a response rate of 37%; patients with c-KIT exon 11 mutations have a 5% response rate).

Adverse Effects
The main adverse effects of sunitinib are shared by all antiangiogenic inhibitors: bleeding, hypertension, proteinuria, and, uncommonly, arterial thromboembolic events and intestinal perforation. However, because sunitinib is a multitargeted TKI, it has a broader adverse effect profile than bevacizumab. Fatigue affects 50%–70% of patients and may be disabling. Hypothyroidism occurs in 40%–60% of patients. Bone marrow suppression and diarrhea also are common side effects; severe neutropenia (neutrophils < 1000/mL) develops in 10% of patients. Less common side effects include hepatotoxicity, congestive heart failure and PPES. It is essential to check blood counts and thyroid function at regular intervals. Periodic echocardiograms also are recommended.

Antiangiogenic Small-Molecule Kinase Inhibitors

Sunitinib

Mechanism of Action
Sunitinib is a small-molecule, orally bioavailable inhibitor of multiple kinases, including VEGFR2.

ADME
The typical treatment cycle of sunitinib is 4 weeks on treatment followed by 2 weeks off. The dosage and schedule of sunitinib can be decreased in patients with adverse effects. More recently, a 2-week on/1-week off schedule has proven to be better tolerated and as effective as the original treatment schedule. Sunitinib is metabolized by CYP3A4 to produce an active metabolite, SU12662, the t½ of which is 80–110 h; steady-state levels of the metabolite are reached after about 2 weeks of repeated administration of the parent drug. Further metabolism results in the formation of inactive products. The pharmacokinetics of sunitinib are not affected by food intake.

Therapeutic Uses
Sunitinib has activity in metastatic renal cell cancer, producing a higher response rate and a longer progression-free survival than seen with IFN or bevacizumab. Sunitinib is also approved for the treatment of pancreatic NETs and of GIST in patients who have developed resistance to imatinib as a consequence of c-KIT mutations. Specific c-KIT mutations correlate with the degree of response to sunitinib (e.g., patients with c-KIT exon 9 mutations have a response rate of 37%; patients with c-KIT exon 11 mutations have a 5% response rate).

Adverse Effects
The main adverse effects of sunitinib are shared by all antiangiogenic inhibitors: bleeding, hypertension, proteinuria, and, uncommonly, arterial thromboembolic events and intestinal perforation. However, because sunitinib is a multitargeted TKI, it has a broader adverse effect profile than bevacizumab. Fatigue affects 50%–70% of patients and may be disabling. Hypothyroidism occurs in 40%–60% of patients. Bone marrow suppression and diarrhea also are common side effects; severe neutropenia (neutrophils < 1000/mL) develops in 10% of patients. Less common side effects include hepatotoxicity, congestive heart failure and PPES. It is essential to check blood counts and thyroid function at regular intervals. Periodic echocardiograms also are recommended.

Sorafenib

Mechanism of Action and Therapeutic Use
Sorafenib, like sunitinib, is an orally bioavailable inhibitor of multiple protein kinases. Sorafenib is the only drug currently approved for treatment of patients with hepatocellular carcinoma. Sorafenib also is approved in patients with metastatic renal cell cancer, but sunitinib and pazopanib are generally preferred first-line therapies (see previous discussion and below).

ADME
Sorafenib has activity in metastatic renal cell cancer, producing a higher response rate and a longer progression-free survival than seen with IFN or bevacizumab. Sunitinib is also approved for the treatment of pancreatic NETs and of GIST in patients who have developed resistance to imatinib as a consequence of c-KIT mutations. Specific c-KIT mutations correlate with the degree of response to sunitinib (e.g., patients with c-KIT exon 9 mutations have a response rate of 37%; patients with c-KIT exon 11 mutations have a 5% response rate).

Adverse Effects
The main adverse effects of sunitinib are shared by all antiangiogenic inhibitors: bleeding, hypertension, proteinuria, and, uncommonly, arterial thromboembolic events and intestinal perforation. However, because sunitinib is a multitargeted TKI, it has a broader adverse effect profile than bevacizumab. Fatigue affects 50%–70% of patients and may be disabling. Hypothyroidism occurs in 40%–60% of patients. Bone marrow suppression and diarrhea also are common side effects; severe neutropenia (neutrophils < 1000/mL) develops in 10% of patients. Less common side effects include hepatotoxicity, congestive heart failure and PPES. It is essential to check blood counts and thyroid function at regular intervals. Periodic echocardiograms also are recommended.
**Adverse Effects**
Sorafenib-treated patients can experience the vascular toxicities seen with other antiangiogenic medications described under bevacizumab. More common adverse effects include fatigue, nausea, diarrhea, anorexia, rash, and palmar-plantar erythrodysesthesias; uncommonly, bone marrow suppression, Gl perforation, and cardiomyopathy occur.

**Pazopanib**
Pazopanib is a kinase inhibitor of VEGFR-1, -2, and -3 as well as FGFRs, KIT, LCK, PDGFR, and other kinases implicated in pathologic angiogenesis and cancer progression. Pazopanib is approved for the treatment of patients with advanced renal cell cancer and advanced STS after prior chemotherapy. It has less toxicity and equivalent efficacy to sunitinib in patients with treatment-naive metastatic renal cancer and therefore has become the preferred first-line treatment of many patients. Pazopanib is orally bioavailable, metabolized mostly by CYP3A, and eliminated with a t1/2 of 31 h. Major adverse effects include hypertension, thrombotic and hemorrhagic events, Gl perforation, QT prolongation, and cardiomyopathy. Pazopanib carries a black-box warning: It can produce severe and life-threatening hepatotoxicity; as a consequence, pazopanib should not be used in elderly patients or those with preexisting liver function test abnormalities.

**Other Receptor Kinase Inhibitors With Antiangiogenic Effects**
Axitinib is a kinase inhibitor of VEGFR-1, -2, and -3 that are implicated in pathologic angiogenesis, tumor growth, and cancer progression. Axitinib is approved for the treatment of patients with advanced RCC after failure of one prior systemic therapy. Axitinib is orally bioavailable, metabolized mainly by CYP3A4/5, and eliminated with a variable t1/2 of 2.5 to 6.1 h. Major adverse effects include hypertension, thrombotic and hemorrhagic events, and Gl perforation similar to those of the anti-VEGF bevacizumab (see previous discussion).

Lenvatinib inhibits the protein kinase activities of VEGFR-1, -2, and -3 as well as FGFRs, PDGFR, and other kinases that are implicated in pathologic angiogenesis and cancer progression. Lenvatinib is approved for the treatment of patients with recurrent or metastatic differentiated thyroid cancer and in combination with everolimus for patients with advanced renal cell cancer. Lenvatinib is orally bioavailable, metabolized by CYP3A, and eliminated with a t1/2 of 28 h. Major adverse effects include hypertension, thrombotic and hemorrhagic events, hepatotoxicity, Gl perforation, and QT prolongation.

Regorafenib inhibits the protein kinase activities of RET, VEGFR1-3, KIT, PDGFR, FGFR1/2, TIE2, RAF1, BRAF, and ABL at concentrations that can be achieved clinically. Several of these kinases are implicated in pathologic angiogenesis and malignant progression. Regorafenib is approved for the treatment of patients with mCRC after previous chemotherapy, anti-VEGF therapy, or anti-EGFR therapy and for patients with locally advanced, unresectable, or metastatic GIST after imatinib or sunitinib. Regorafenib is orally bioavailable, metabolized mostly by CYP3A, and eliminated with a variable t1/2 of about 28 h (range 14 to 38 h). Major adverse effects include hepatotoxicity, hypertension, thrombotic and hemorrhagic events, Gl perforation, QT prolongation, and wound-healing complications. As expected for an agent metabolized by CYP3A4, strong inducers and strong inhibitors of CYP3A4 must be avoided (see pathobiology, previously discussed, for details).

IV. Targeting the Immune System

**Immune Checkpoint Inhibitors**
Recent striking successes of cancer immunotherapy have given credence to the long-held hope that the immune system may be unleashed to treat cancer. The conceptual breakthrough is based on the discovery of inhibitory signals that limit T-cell activation, so-called immune checkpoints. The discovery of receptors, ligands, and their function in the control of immune cell activity during the past two decades led to the development of clinically effective monoclonal antibodies that enable T cells to recognize and eradicate cancer cells with acceptable adverse effects (Figure 67–5).

**HISTORY Immune Checkpoint Inhibitors**
The discovery of the TCR and of costimulatory signal pathways in the period from 1982 to 1992 defined essential requirements for T-cell activation during antigen presentation: In addition to the antigen-TCR interaction, CD28 on T cells binds to B7 proteins on APCs (see Figure 67–5; see also Figures 35–2 and 35–4). The finding, in the mid-1990s, of coinhibitory molecules that can dampen T-cell activation revealed a potential mechanism for drugs to modulate immune checkpoints and alter antitumor immune activity. TCR activation induces expression of the inhibitory CTLA-4, a CD28 homolog with higher affinity for the B7 ligands than CD28. CTLA-4 inhibits T-cell activation to control autoimmune tissue damage. PD-1, another inhibitory molecule expressed on T cells after their activation, and PD-L1, the ligand for PD-1, were described in the early 2000s. It became obvious that T cells present in human tumors were being inhibited by factors in the tumor tissues: TILs harvested from patients and activated exogenously showed efficacy and paved the way for targeting immune inhibition. Improved survival of patients with metastatic melanoma after anti–CTLA-4 treatment led to FDA approval of ipilimumab in 2011; anti-PD-1 and anti-PD-L1 were approved in 2014. Clinical trials in multiple types of cancer have been ongoing since then and have led to the approval of immune checkpoint inhibitors for additional indications (Monteiro, 2015) described in this section.

Blocking immune checkpoints on cytotoxic T cells enables them to eradicate cancer cells that express antigens recognized by the T cells. Sustained eradication of metastatic melanoma in a significant number of patients was an impressive outcome of initial clinical trials with a monoclonal antibody, ipilimumab, which is an immune checkpoint inhibitor (Robert et al., 2013). Note that immune checkpoint inhibition is distinct from conventional approaches such as vaccination with a known antigen (to generate T cells that recognize cells expressing the antigen), nonspecific stimulation of T cells, or approaches using antigen-responsive T cells that express a specific chimeric antigen receptor (CAR). The different approaches are described next.

**Mechanisms of T-Cell Activation**
Antigen-mediated activation of T cells is initiated by engagement of the TCR with antigen presented on MHC protein on the surface of an APC, “signal 1.” In addition, engagement of CD28 costimulatory molecules on T cells is required for effective T-cell activation that includes cell proliferation, migration, and production of cytokines. This “signal 2” is provided by B7 surface proteins on APCs, for example, CD80 or CD86 (Figures 35–4 and 67–5). T-cell activation is tightly controlled by immune-suppressive cells and cytokines as well as by coinhibitory molecules present on T cells, such as CTLA-4 or PD-1 (Figure 67–5). CTLA-4 is expressed by activated CD4 and CD8 T cells and competes with costimulatory CD28 for binding to the B7 protein ligands. Binding of CTLA-4 to B7 proteins interrupts the initial CD28 costimulatory signals and serves as an early negative regulator of the T-cell activation responses, that is, an immune checkpoint. Additional control of T-cell activity is provided by later inhibitory signals through other molecules, such as PD-1 that binds the ligand PD-L1. PD-1 is mainly expressed by activated CD4 and CD8 T cells as well as APCs.

Blocking monoclonal antibodies to CTLA-4, PD-1, or PD-L1 are currently used to neutralize coinhibitory receptors during T-cell priming (CTLA-4), to maintain cancer antigen-specific T-cell function, and to provide a sustained T-cell response (PD-1) that includes increased production...
Mechanism of Action
Iplimunab blocks the interaction of CTLA-4 with B7 ligands on APCs and thereby augments T-cell activation (Figure 67–5). Inhibition of CTLA-4 signaling can also inhibit regulatory T-cell function that dampens cytotoxic T-cell activity and thus increases the antitumor immune response further (Mellman et al., 2011).

ADME
Iplimunab is administered intravenously and shows linear pharmacokinetics in the dose range of 0.3 to 10 mg/kg, with a terminal half-life of 15.4 days.

Therapeutic Uses
A pivotal 2010 trial in patients with metastatic melanoma showed improved median overall survival after ipilimumab treatment (Hodi et al., 2010). This trial led to FDA approval of ipilimumab for the treatment of metastatic melanoma. Further studies showed that some patients had clinical responses that lasted for 10 or more years (Schadendorf et al., 2015). The tumor response can take several months to manifest, and tumors may increase in size during this period, in part due to the evolving inflammatory reaction (Mellman et al., 2011). Current recommended dosing of ipilimumab is 3 mg/kg intravenously over 90 min every 3 weeks for a total of four doses for patients with metastatic disease and 10 mg/kg followed by 10 mg/kg every 12 weeks for up to 3 years or until documented disease recurrence or unacceptable toxicity for patients treated in the adjuvant setting.

Adverse Effects
Blockade of CTLA-4 compromises immune tolerance to some normal tissue antigens and provokes inflammatory toxicities, mostly in the skin, pituitary gland, intestine, and liver. The activation of T-cell responses by ipilimumab treatment leads to immune-related toxicities in the majority of patients (73.6%), with 18.6% reaching toxicity grade 3–4 toxicity (Callahan et al., 2016). Adverse effects on the skin (pruritus, rash, vitiligo) and GI tract (diarrhea, colitis) are the most frequent, whereas immune-mediated hepatitis, hypophysitis, and hypo- or hyperthyroidism are less frequent. Withholding treatment because of moderate adverse reactions until return to baseline and high-dose corticosteroids for severe immune-mediated reactions are recommended.

Other Drugs in This Class
Tremelimumab (formerly ticilimumab) is a fully human IgG2 monoclonal antibody that targets CTLA-4; it is under investigation in several clinical trials.

Inhibitors of Programmed Cell Death 1 (PD-1)
Activation of the PD-1 checkpoint pathway in T cells by PD-L1 or PD-L2 evokes a negative regulatory immune response and inactivates T cells (Figure 67–5). Tumor cells can exploit this pathway by presenting PD-L1 ligand to tumor-infiltrating T cells and thus shield the tumor from T cell–mediated destruction. Presentation of PD-L1 to activated T cells results in T-cell exhaustion, whereas antibody-mediated blockade of PD-1 can restore or maintain T-cell antitumor response.

Nivolumab
Mechanism of Action
Nivolumab is a fully human monoclonal IgG4 antibody that blocks the interaction between PD-1 and its ligands.

ADME; Clinical Use
Nivolumab is administered as an intravenous infusion every 2 weeks until the time of disease progression or of unacceptable toxicity. The drug has an elimination half-life of 26.7 days. Nivolumab is FDA approved for the treatment of a variety of cancers, currently including advanced melanoma, previously treated advanced NSCLC, RCC, advanced head and neck cancer, and relapsed/refractory classical Hodgkin lymphoma. Quite strikingly, nivolumab provided an overall response rate of 87% in patients with...
Pembrolizumab

Pembrolizumab (formerly called lambrolizumab or MK-3475) is a humanized monoclonal IgG4-k isotype antibody that blocks interaction between PD-1 and its ligands. This humanized antibody has a mouse variable region grafted onto a human antibody framework and shows high affinity toward PD-1 receptors of humans and other primates but no appreciable affinity for mouse or rat PD-1.

The FDA has extended the approval for pembrolizumab to any cancer with mismatch repair (MMR) deficiency or high microsatellite instability (MSI-H). The defects in DNA repair lead to a higher mutation load and increased generation of mutant protein antigen by cancer cells that can activate the immune system. This first cancer tissue-agnostic approval extends immune checkpoint inhibitor treatment to subsets of patients with hereditary CRC due to Lynch syndrome (MSI-H) and up to 20% of patients with sporadic colon cancer. The frequency is less in endometrial, ovarian and pancreatic cancers and will require testing of each patient's tumor to assess suitability of the treatment.

**ADME: Clinical Use**

The recommended treatment schedule for pembrolizumab is 2 mg/kg (or a 200-mg flat dose) as an intravenous infusion over 30 min every 3 weeks. The elimination half-life is 26 days. In clinical trial, pembrolizumab demonstrated an overall response rate of 26% in patients with iplimumab-pretreated and refractory advanced melanoma (Hamid et al., 2013; Robert et al., 2014). Pembrolizumab is more effective and less toxic than ipilimumab in patients with either treatment-naive or BRAF inhibitor–pretreated melanoma. Pembrolizumab is currently approved for the treatment of patients with advanced melanoma, unresectable or metastatic melanoma in patients previously treated with ipilimumab, PD-L1–positive NSCLC (either prior to or after platinum-containing chemotherapy), and chemotherapy-refractory head and neck cancer. Significant antitumor activity has also been found relative to chemotherapy in patients with metastatic head and neck cancer. pembrolizumab is also being evaluated for efficacy toward cancers of the head and neck, stomach, lung, and ovary, as well as hepatocellular cancer.

**Adverse Effects**

The most common adverse effects, experienced by more than 20% of patients, are fatigue, cough, nausea, pruritus, rash, decreased appetite, constipation, arthralgia, and diarrhea. An additional 10% of patients may experience complications with infections. Serious adverse events include immune-mediated inflammation, specifically pneumonitis, colitis, hepatitis, and hypophysitis and both hyper- and hypothyroidism. Withholding treatment and administration of systemic corticosteroids for grade 2 or discontinuing treatment with more severe adverse effects is recommended. Because human IgG4 can cross the placenta, the benefit from pembrolizumab treatment should be balanced with the potential fetal risk in a pregnant woman.

**Antagonists of PD-1 Ligand 1**

Programmed cell death 1 has two ligands, PD-L1 and PD-L2, each with distinct expression profile. The PD-L1 ligand is expressed on APCs, T cells, B cells, and nonhematopoietic cells, which can include cancer cells (Figure 67–5). Expression of PD-L2 is restricted to APCs, macrophages, myeloid dendritic cells, and mast cells. Clinical trial results are promising with drugs targeting PD-L1.

**Atezolizumab**

**Mechanism of Action**

Atezolizumab, also known as MPDL3280A, is a fully human IgG1 monoclonal antibody that blocks the interaction of PD-L1 with PD-1 and B7-H1. PD-L1 is expressed in many cancers and thus can suppress the activation of cytotoxic T cells that enter the tumor. Atezolizumab can remove this inhibitory effect and promote an effective antitumor response.

**ADME**

Atezolizumab is administered as an intravenous infusion over 60 min every 3 weeks. The terminal half-life is 27 days.

**Clinical Use**

Atezolizumab is indicated for conventional treatment-resistant metastatic NSCLC as well as locally advanced or metastatic urothelial cancer.

**Adverse Effects**

The most common adverse effects in 20% or more of patients with metastatic NSCLC are fatigue, decreased appetite, dyspnea, cough, nausea, musculoskeletal pain, and constipation. Patients with urothelial carcinoma may report urinary tract infection. Possible immune-related adverse effects include hepatitis, colitis, hypophysitis, thyroid disorders, adrenal insufficiency, type 1 diabetes mellitus, pancreatitis, myasthenia gravis, Guillain-Barré syndrome, and ocular inflammation; these may may require discontinuation of treatment. Due to potential embryo-fetal toxicity, female patients should be advised accordingly.

**Other Anti–PD-L1 Antibodies**

Durvalumab (approved in 2017 for metastatic urothelial cancer) and avalumab (approved in 2017 for metastatic urothelial and Merkel cell cancer) are also being evaluated for efficacy toward cancers of the head and neck, stomach, lung, and ovary, as well as hepatocellular cancer.

**Combination of Anti–PD-1 and Anti–CTLA4**

Because anti–CTLA-4 and anti–PD-1 target distinct immune checkpoints during T-cell activation, preclinical studies have shown that concurrent targeting of CTLA-4 and PD-1 significantly improves therapeutic efficacy when compared to effects of single agents (Curran et al., 2010). In patients with advanced melanoma, the combination of ipilimumab and nivolumab produces a positive response in more than 50% of the patients with an acceptable level of adverse effects, although the combination therapy significantly increased the rate of rare but fatal myocarditis (combination 0.17%; nivolumab < 0.01%) (Johnson et al., 2016). The 1- and 2-year overall survival rates were 94% and 88%, respectively (Wolchok et al., 2013). Thus, combinations of immune checkpoint inhibitors with different targets may become the standard of care in various solid as well as hematologic malignancies (Mellman et al., 2016). Most important, combination immunotherapy will likely be more effective than most other forms of treatment of patients with metastatic disease (Restifo et al., 2016).

**Cytokines to Stimulate Immune Responses**

**Interleukin 2**

Of the 70 or so proteins and glycoproteins that are classified as cytokines, only IFN (Chapters 34 and 35) and IL-2 are in routine clinical use, often for actions against cancer.

Activated CD4+ T cells are the primary producers of IL-2. The functions of IL-2 are myriad; amongst other roles, IL-2 promotes the growth of T cells and NK cells, stimulates the proliferation of and antibody production by B cells, and drives the development of Treg cells (mediators...
of tolerance and suppression). As noted by Liao and colleagues (2013), "IL-2 has broad essential biological actions, not only driving T cell proliferation and modulating effector cell differentiation, but also limiting potentially dangerous autoimmune reactions." This statement provides a general rationale for the clinical use of IL-2 and the likelihood that IL-2 administration might also engender adverse effects.

**Mechanism of Action**
Interleukin 2 stimulates the proliferation of activated T cells and the secretion of cytokines from NK cells and monocytes. IL-2 stimulation increases cytotoxic killing by T cells and NK cells.

Interleukin 2 is a 133–amino acid glycoprotein (molecular weight ~ 15 kDa) produced by activated T cells and NK cells; it promotes activated T-cell proliferation and enhanced killing by NK cells. Responsiveness depends on expression of the IL-2R. The receptor comprises three independently expressed membrane monospans, α, β, and γ, which can assemble in several combinations to produce working receptors of varying affinities. These monospans are variously expressed in lymphohematopoietic cells, lack C-terminal protein kinase activities, and transduce signals via coupling to Jak proteins (Figure 67–6). Nearly all types of tumor cells lack receptor expression and are unresponsive to IL-2.

**ADME**
Interleukin 2 (as recombinant IL-2, aldesleukin) is administered intravenously. The serum t½ of IL-2 after intravenous administration has an α phase of about 15 min and a β phase of about 90 min. IL-2 is excreted in the urine as an inactive metabolite.

**Therapeutic Uses**
Aldesleukin possesses the biological activities of native human IL-2. The drug is approved for use in patients with metastatic renal cell cancer and metastatic melanoma. High-dose IL-2 produces an overall response rate of 15%–25% in patients with renal cell cancer; 8% achieve a complete response. In patients with metastatic melanoma, high-dose IL-2 induces an overall response rate of 16%–22%, and 6% achieve a complete response. In both instances, responses last a median of about 5 years. Low-dose IL-2 also produces responses, but few are complete responses, and the duration may be less than with high-dose IL-2.

**Adverse Effects**
Interleukin 2 toxicities are dominated by the capillary leak syndrome, in which intravascular fluid leaks into the extravascular space, producing hypotension, edema, respiratory difficulties, confusion, tachycardia, oliguric renal failure, and electrolyte problems. Symptoms include fever, chills, malaise, nausea, vomiting, and diarrhea. Laboratory abnormalities include thrombocytopenia, abnormal liver function tests, and neutropenia. Most patients develop a pruritic skin rash. Hypothyroidism may occur. Arrhythmias are a rare complication. These toxicities can be life threatening, yet nearly all are reversible within 24–48 h of discontinuing therapy. Patients should have normal renal and hepatic function before beginning therapy and should be closely supervised in an inpatient facility capable of care at the intensive care unit level during drug administration.

---

**A. IL-2 receptors**

| Kₐ of receptor complex for IL-2 (M) |
|-------------------------|--------|
| High                    | 10⁻¹¹  |
| Medium                  | 10⁻⁸   |
| Low                     | 10⁻⁸   |

**B. IL-2 receptor signaling**

Diagram showing the interaction of IL-2 with Jak proteins, resulting in phosphorylation of nuclear substrates, STAT5-dependent gene regulation, and ERK/MAPK pathway.

---

**Figure 67–6** A pharmacologist’s view of IL-2 receptors, their cellular signaling pathways, and their inhibition. A. IL-2 receptors. The IL-2 receptor has three components: an α chain, a 55-kDa protein (CD25) involved mainly in IL-2 binding; a β chain, a 75-kDa protein that binds to Jak1; and a γ chain, a 64-kDa protein that signals via Jak3. These components combine as shown to produce receptors of varying affinities and with different capacities for intracellular signaling. The γ chain is a component of many cytokine receptors (IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21). Resting T cells have a low density of IL-2Ra; however, activation of the TCR (see Figure 35–2) and IL-2, itself, induce IL-2Ra expression. IL-2Ra can also be induced by a large variety of cytokines, viruses, and activators of PKc. The β and γ monospans are constitutively expressed on many lymphohematopoietic cells, and their expression can also be regulated. Tumor cells generally lack receptor expression and are unresponsive to IL-2.

- Binding of an SHC adapter/scaffolding protein that is the platform for activation of the Ras-MAPK pathway and the PI3K pathway
- Recruitment and phosphorylation of STAT5 and to Jak1, Jak2, and Jak3 (red boxes and T bars)
**Cancer Vaccines**

Vaccination against cancer antigens has shown little efficacy with the exception of two approaches that were approved by the FDA in 2010 (*sipuleucel-T*) and in 2015 (*T-VEC*).

**Sipuleucel-T**

Sipuleucel-T is a cell-based approach designed to induce an immune response against PAP, which is expressed in most prostate cancers. This autologous cellular immunotherapy is generated from a patient's peripheral blood cells, which are isolated by leukapheresis. The cells are exposed to a human recombinant protein, PAP–GM-CSF. APCs present amongst the blood cells are thought to take up and process PAP and direct the immune response toward the antigen. A patient receives the treated cells by infusion on three occasions at 2-week intervals. Treatment is approved for patients with minimally symptomatic, hormone-refractory, metastatic prostate cancer. Adverse effects include acute infusion reactions, which can be reduced by premedication with acetaminophen and antihistamine.

**T-Vec**

T-VEC (talimogene laherparepvec) is an oncolytic herpesvirus that replicates within tumors and expresses GM-CSF. Tumor antigens are released after virally induced cell death, and the presence of GM-CSF can promote an antitumor immune response. T-VEC is approved for the local treatment of unresectable cutaneous and nodal lesions in patients with melanoma. T-VEC may synergize with immune checkpoint inhibitor treatment. Adverse effects are influenza-like symptoms and injection site pain.

**Chimeric Antigen Receptor T Cells**

Treatment of patients with B-cell leukemias or lymphoma with receptor-engineered T cells has produced striking successes. CARs contain the antigen-binding domain of a monoclonal antibody to recognize foreign recognition of the targeted tumor antigen coupled to intracellular domains capable of activating T cells (Figure 67–7). When expressed in T cells, these CARs recognize cell surface antigens and activate T cells independent of antigen presentation by a MHC molecule as required for physiologic antigen presentation (see Figures 35–2 and 67–5). In initial studies, CAR-expressing T cells were targeted to NY-ESO-1, a tumor antigen of the cancer/testis family that is highly expressed on many poor-prognosis melanoma cells. The CAR T cells showed long-lasting efficacy (>3 years) in some patients with metastatic melanoma. CAR targeting CD19, a B-cell antigen, also resulted in striking efficacy in patients with B-cell leukemias (Kebanoff et al., 2016). The approval of CD19 CAR-T cells (*tisagenlecleucel-T;* previously named CTL019) has been recommended, based on data showing >80% remissions of relapsed or refractory B-cell ALL during treatment. Other CARs targeting CD22 and B-cell maturation antigen (BCMA) have shown efficacy and are currently under investigation.

**Future Challenges of Immunotherapy**

The potential for immunotherapies to augment conventional chemotherapy, pathway-targeted treatment, and radiotherapy will require detailed exploration and will be a common theme in the design of future clinical trials (Ebert et al., 2016; Hughes et al., 2016). The recent identification of multiple negative and positive immune-modulatory pathways that can be targeted is leading to development of new drugs that will require testing as monotherapy and combination with each other as well as with conventional treatments. This new class of cancer treatment presents a new set of adverse effects (e.g., fulminant myocarditis caused by a combination of immune checkpoint inhibitors; Johnson et al., 2016) that must be understood mechanistically before rational combination strategies can be developed.

**Inhibitors of Poly (ADP-Ribose) Polymerase**

DNA damage-repair genes are frequently inactivated in human cancer. PARP1 is the product of one such gene. PARP1 is a nuclear protein that transfers ADP-ribose from NAD+ to target proteins, and this poly (ADP-ribose)ylation (or PARylation) of nuclear proteins by PARP1 plays a significant role in the DNA damage response (Tallis et al., 2014). Inactive PARP1 associates with chromatin and helps to create a compact chromatin structure in the nucleosome. DNA damage (e.g., strand breaks) mobilizes the enzyme, promoting PARP-mediated PARylation, with the result that chromatin relaxes in the area of damage. The mechanisms of relaxation are the PARylation of PARP1 itself, and of histones and other chromatin-associated proteins, resulting in their dissociation from DNA. PARylation produces branching chains up to 200 ADP-ribose units in length. These chains provide docking centers for the localized recruitment of PAR-binding factors and thence of DNA repair enzymes (e.g., DNA polβ, DNA ligase III) and proteins that help to maintain an inactive environment in the open chromatin region while repairs are made to the damaged DNA. The synthesis and degradation of PAR chains in vivo is tightly regulated, with the chains having half-lives measured in minutes (Wei and Yu, 2016). Excessive activation of PARP1 leads to depletion of the cellular pool of NAD+ and to cell death; teleologically, this could be viewed as a means of preserving genomic integrity by removing cells with heavily damaged DNA.

Deficient PARP1 activity leads to defective DNA repair. However, PARP-deficient cells are still able to carry out DNA repair through a different mechanism: homologous recombination. The protein machinery for homologous recombination repair includes the breast cancer susceptibility genes BRCA1 and BRCA2, suggesting that cells with diminished or absent BRCA1/2 function could be unusually susceptible to the inhibition of PARP activity. BRCA1/2 mutations predispose carriers to breast, ovarian, and other cancers that can be resistant to chemotherapy. BRCA-deficient cells are more dependent on PARP1 and base excision repair to maintain genomic integrity; BRCA1/2-deficient cancer cells are less able to carry out repair and ultimately die; inhibition of PARP could accelerate this process. It is noteworthy that PARPs catalyze PARylation of a number of proteins that regulate cellular processes beyond DNA damage repair; these extra-chromatin actions may contribute to the clinical efficacy and adverse effects of PARP inhibitors. Inhibitors of PARP are designed to compete with NAD+ at its binding site on the PARP enzyme. Olaparib and rucaparib are approved for the treatment of patients with advanced ovarian cancer.

**Figure 67–7** Chimeric antigen receptor (CAR) T cell activation by a target antigen on cancer cells. T cells are harvested from a cancer patient and transduced with a CAR expression vector. Elements in a CAR: extracellular, single-chain antibody fragment of the variable domain (scFv) that recognizes the targeted antigen; intracellular co-stimulatory domain (e.g. from CD28); intracellular signaling domain of the TCR. CD19 is shown as an antigen example. APC-mediated stimulation of T cells is depicted for comparison (see figure 67–5).
Olaparib

Olaparib is an orally bioavailable inhibitor of PARP enzymes.

**ADME**

Olaparib is rapidly absorbed after oral administration and metabolized primarily by CYP3A4, yielding a t\(_{1/2}\) of about 12 h. Drug exposure is increased or reduced when administered in combination with a CYP3A4 inhibitor or inducer, respectively.

**Therapeutic Uses; Adverse Effects**

Olaparib is EMA and FDA approved as monotherapy in patients with germline BRCA-mutated, advanced, ovarian cancer who have been treated with three or more prior lines of chemotherapy. Adverse effects include GI upset (nausea and vomiting) and loss of appetite; fatigue; muscle and joint pain; low blood cell counts and anemia; and occasionally leukemia. Potentially fatal MDS and pneumonitis have been observed.

Rucaparib

Rucaparib is a benzimidazole derivative that inhibits PARP1. Rucaparib is FDA approved for treatment of advanced ovarian cancer in patients exhibiting deleterious BRCA mutations who have been treated with at least two prior chemotherapies. The drug was approved in conjunction with the approval of a gene-sequencing test that detects BRCA1/2 mutations in patient tumor tissue.

**Clinical Use; Adverse Effects**

The drug is administered orally but should not be given until the patient has recovered from any hematological toxicity caused by previous chemotherapy. CYP2D6 metabolizes rucaparib, yielding a half-life of about 18 h. Adverse effects include GI upset and abdominal pain, fatigue, and decreased appetite. MDS and AML are rare but serious adverse effects (<1%). This agent may cause fetal harm and should not be administered to pregnant females or used by nursing mothers.

**BCL2 Inhibitors**

The BCL2 protein family comprises more than 20 proteins that govern mitochondrial outer membrane permeabilization and control programmed cell death (apoptosis). Proteins in this family can be either pro- or antiapoptotic depending on their content of BCL2 homology domains (BH1 to 4). Proapoptotic proteins contain a BH3 domain that is necessary for dimerization with other proteins of the BCL2 family. Antiapoptotic proteins contain BH1 and BH2. The balance of these interacting proteins controls mitochondrial outer membrane permeabilization, cytochrome c release, and the activation of caspases that leads to apoptosis (Figure 67–8). BCL2 promotes cellular survival by inhibiting proapoptotic proteins like BIM, BAX, and BAK and is overexpressed in CLL and some other tumors where it can support tumor cell survival and resistance to cancer treatments.

**Venetoclax**

**Mechanism of Action**

Venetoclax is a first-in-class, orally bioavailable, small-molecule inhibitor of BCL2. It was designed as a BH3 mimic that inhibits BCL2 interaction with the proapoptotic BH3-only family members, such as BIM, BID, and BAD. In vitro, venetoclax inhibits BCL2 action with an IC\(_{50}\) of less than 0.01 nM and with a selectivity of two to three orders of magnitude over other BCL2 family members. In the presence of venetoclax, BH3-only proteins can translocate to mitochondria and initiate BAX/BAK-dependent apoptosis. Overexpression of BCL2 occurs in CLL cells, where it supports tumor cell survival and resistance to chemotherapeutic agents. Thus, venetoclax helps restore apoptosis in these cells.

**ADME; Therapeutic Use; Adverse Effects**

Oral absorption is significantly improved 3- to 5-fold by administration with a meal. Venetoclax, a Pgp substrate, is metabolized by CYP3A4/5; concomitant use of CYP3A inhibitors or inducers and Pgp inhibitors should be avoided (see previous discussion of palbociclib for details). The elimination half-life is 18–26 h. Venetoclax is approved for the treatment of patients with CLL with a 17p deletion. The most common adverse effects are neutropenia, diarrhea, nausea, anemia, upper respiratory tract infection, thrombocytopenia, and fatigue. Venetoclax should not be administered during pregnancy or breastfeeding until further data are available.

**Thalidomide and Lenalidomide**

Thalidomide and lenalidomide have a most unusual history and a multiplicity of biological and immunological effects. Thalidomide originally was used for the treatment of pregnancy-associated morning sickness.
but was withdrawn from the market due to teratogenicity and dysmelia (stunted limb growth). It reentered clinical practice for treatment of erythema nodosum leprosum (see Chapter 60). Further research revealed its antiangiogenic and immunomodulatory effects. At least four distinct mechanisms have been proposed to explain its antitumor activity, which are summarized in Figure 67–9 and enumerated in its legend.

Both thalidomide and lenalidomide possess potent activity in patients with newly diagnosed and heavily pretreated relapsed/refractory MM. Lenalidomide also is approved for its activity in the 5q− subset (or del(5q) subset) of MDS. A specific gene array profile identifies patients with MDS who lack the 5q− abnormality but respond to lenalidomide. A more recently added derivative of thalidomide is pomalidomide, approved for treatment of patients with MM resistant to lenalidomide.

**Thalidomide**

**ADME**

Thalidomide exists at physiological pH as a racemic mixture of cell-permeable and rapidly interconverting nonpolar S(−) and R(+) isomers. The R-enantiomer is associated with the teratogenic and biological activities, while the S accounts for the sedative properties of thalidomide. In treating MM, doses usually are escalated by 200 mg/d every 2 weeks until dose-limiting side effects (sedation, fatigue, constipation, or a sensory neuropathy) appear. With extended treatment, the neuropathy may necessitate dose reduction or discontinuation of treatment for a period of time. Thalidomide absorption from the GI tract is slow and highly variable. It distributes throughout most tissues and organs, without significant binding to plasma proteins. The enantiomers are eliminated with a t\(_{1/2}\) of about 6 h, mainly due to spontaneous hydrolysis in all body fluids; the S-enantiomer is cleared more rapidly than the R-enantiomer. Thalidomide and its metabolites are excreted in the urine, while the nonabsorbed portion of the drug is excreted unchanged in feces. The inactive hydrolysis products undergo CYP-mediated metabolism. Longer plasma t\(_{1/2}\) is reported at the highest doses (1200 mg daily). No dose adjustment is necessary in the presence of renal failure.

**Lenalidomide**

Lenalidomide constitutes the lead compound of immunomodulatory thalidomide derivatives. Lenalidomide induces the ubiquitination and degradation of target proteins by the E3 ubiquitin ligase CRL4CRBN (Fink and Ebert, 2015). Target proteins in MM cells are IKZF1/3, which are crucial for cell survival (Lu et al., 2014) (Figure 67–9). In MDS, casein kinase 1A1 is the target protein (Kronke et al., 2015). Cellular effects of lenalidomide include direct suppression of tumor cell growth in culture, T-cell and NK-cell activation, suppression of TNFα and other cytokines, antiangiogenesis, and promotion of HSC differentiation.

**ADME**

The standard dosage of lenalidomide is 25 mg/d for 21 days of a 28-day cycle. The drug is rapidly absorbed following oral administration, reaching peak plasma levels within 1.5 h. The t\(_{1/2}\) of parent drug in plasma is 9 h. Approximately 70% of the orally administered dose of lenalidomide is excreted intact by the kidney. Dose adjustments to 10 mg/d for creatinine clearance of 30–50 mL/h and to the same dose every 2 days for creatinine clearance less than 30 mL/h are recommended for patients with renal failure.

**Therapeutic Use**

Lenalidomide exerts potent antitumor activity in MM, MDS, and CLL; this agent causes fewer adverse effects and lacks the teratogenicity of thalidomide.

**Adverse Effects of Thalidomide and Lenalidomide**

Thalidomide is well tolerated at doses less than 200 mg daily. Common adverse effects are sedation and constipation. The most serious adverse effect is peripheral sensory neuropathy, which occurs in 10%–30% of patients with MM or other malignancies in a dose- and time-dependent manner. Thalidomide-related neuropathy is an asymmetrical, painful, peripheral paresthesia with sensory loss, commonly presenting with numbness of toes and feet, muscle cramps, weakness, signs of pyramidal tract involvement, and carpal tunnel syndrome. Although symptoms improve on drug discontinuation, long-standing sensory loss may not reverse. Particular caution should be applied in patients with preexisting neuropathy (e.g., related to diabetes) or prior exposure to drugs that can cause peripheral neuropathy (e.g., vinca alkaloids, bortezomib). Thalidomide enhances the sedative effects of barbiturates and alcohol and the cataleptic effects of chlorpromazine. Conversely, CNS stimulants (such as methylamphetamine and methylphenidate) counteract the depressant effects of thalidomide.

Adverse effects of lenalidomide are less severe; it causes little sedation, constipation, or neuropathy. Lenalidomide depresses bone marrow function and is associated with significant leukopenia (20% of patients). Hepatotoxicity and renal dysfunction are rare. In some patients with CLL, lenalidomide causes dramatic lymph node swelling and tumor lysis (tumor flare reaction). Patients with renal dysfunction are prone to this reaction; thus, patients with CLL should be started at lower doses of 10 mg/d, with escalation as tolerated. Patients with CLL should receive pretreatment hydration and allopurinol to avoid the consequences of tumor swelling and tumor lysis. A negative interaction with rituximab, an anti-CD20 antibody, may result from lenalidomide's downregulation of CD20, an interaction that has clinical implications for their combined use in lymphoid malignancies.

---

**Figure 67–9** Overview of proposed mechanisms of antitumor activity of thalidomide and its derivatives. Some biological hallmarks of the malignant phenotype are indicated in blue boxes. The proposed sites of action for thalidomide (letters inside red and green circles) are hypothesized to also be operative for thalidomide derivatives. A. Direct anti-MM effect on tumor cells, including G₁ growth arrest or apoptosis, even against MM cells resistant to conventional therapy. This is due to the disruption of the antiapoptotic effect of BCL2 family members, blocking NF-κB signaling, and inhibition of the production of IL-6. Mechanistic studies show that lenalidomide can kill MM cells by inducing E3 ubiquitin ligase CRL4CRBN-mediated ubiquitination and degradation of the crucial IKZF1 & 3 (zinc finger transcription factors). B. Inhibition of MM cell adhesion to bone marrow stromal cells partially due to the reduction of IL-6 release. C. Decreased angiogenesis due to the inhibition of cytokine and growth factor production and release. D. Enhanced T-cell production of cytokines, such as IL-2 and IFN-γ, that increase the number and cytotoxic functionality of NK cells.
Thalidomide and lenalidomide increase the risk for thromboembolic events, including deep vein thrombosis, stroke, and myocardial infarction, which occur with increased frequency in combination with glucocorticoids and with anthracyclines. Anticoagulation and antiplatelet medication reduce this risk and are indicated in patients with risk factors for clotting.

**Pomalidomide**

Pomalidomide, a thalidomide congener, is indicated for the treatment of patients with MM who have received at least two prior therapies including lenalidomide. Adverse effects are similar to those of thalidomide. Poma- lidomide in contraindicated during pregnancy and in females who may become pregnant. As a consequence, this drug is available only under a pregnancy control system to ensure that recipients are not pregnant and are using effective birth control.

**Proteasome Inhibitors**

**First Generation**

**Bortezomib** is a first-generation inhibitor of proteasome-mediated protein degradation that has a central role in the treatment of MM.

**Mechanism of Action**

Bortezomib binds to the β5 subunit of the 20S core of the 26S proteasome and reversibly inhibits its chymotrypsin-like activity. This event disrupts multiple intracellular signaling cascades, leading to apoptosis. An important consequence of proteasome inhibition is its effect on NF-κB, a transcription factor that promotes cell damage response and cell survival. Most cellular NF-κB is cytosolic and bound to IκB; in this form, NF-κB is restricted to the cytosol and cannot enter the nucleus to regulate transcription. In response to stress signals resulting from hypoxia, chemotherapy, and DNA damage, IκB becomes ubiquitinated and then degraded via the proteasome. Its degradation releases NF-κB, which enters the nucleus and transcriptionally activates a host of genes involved in cell survival (e.g., cell adhesion proteins, and proliferation (e.g., cyclin-D1) or antiapoptosis (e.g., cIAPs, BCL-2). NF-κB is highly expressed in many human tumors, including MM, and may be a key factor in tumor cell survival in a hypoxic environment and during chemotherapy. Bortezomib blocks proteasomal degradation of IκB, thereby preventing the transcriptional activity of NF-κB and downregulating survival responses.

Bortezomib also disrupts the ubiquitin-proteasomal degradation of p21, p27, p53, and other key regulators of the cell cycle and initiators of apoptosis. Bortezomib activates the cell’s stereotypical “unfolded protein response,” in which abnormal protein conformation activates adaptive signaling pathways in the cell. The composite effect leads to irreversible commitment of MM cells to apoptosis.

**ADME**

The recommended starting dose of bortezomib is 1.3 mg/m² given as an intravenous bolus on days 1, 4, 8, and 11 of every 21-day cycle (with a 10-day rest period per cycle). At least 72 h should elapse between doses. Drug administration should be withheld until resolution of any grade 3 nonhematological toxicity or grade 4 hematological toxicity, and subsequent doses should be reduced 25%. The drug exhibits a terminal t₁/₂ in plasma of 5.5 h. Peak proteasome inhibition reaches 60% within 1 h and declines thereafter, with a t₁/₂ of about 24h. Bortezomib clearance results from the deoration of the parent compound (90%), followed by hydroxylation of the boron-free product by CYPs 3A4 and 2D6; administration of this drug with potent inducers or inhibitors/substrates of CYP3A4 requires caution. No dose adjustment is required for patients with renal dysfunction.

**Therapeutic Uses**

Bortezomib is used as initial therapy for patients with MM and as therapy for patients with MM after relapse from other drugs. It is also approved for treatment of patients with relapsed or refractory MCL. The drug is active in myeloma, including the induction of complete responses in up to 30% of patients when used in combination with other drugs (i.e., thalidomide, lenalidomide, liposomal doxorubicin, or dexamethasone).

**Adverse Effects**

Bortezomib toxicities include thrombocytopenia (28%), fatigue (12%), peripheral neuropathy (12%), neutropenia, anemia, vomiting, diarrhea, limb pain, dehydration, nausea, and weakness. Peripheral neuropathy, the most chronic of the toxicities, develops most frequently in patients with a prior history of neuropathy secondary to prior drug treatment (e.g., thalidomide) or diabetes with or without prolonged use. Dose reductions or discontinuation of bortezomib ameliorates the neuropathic symptoms. Injection of bortezomib may precipitate hypotension, especially in volume-depleted patients, in those who have a history of syncope, or in patients taking antihypertensive medications. Cardiac toxicity is rare, but congestive heart failure and prolonged QT interval have been reported.

**Second Generation**

**Carfilzomib** is a second-generation selective proteasome inhibitor based on a tetrapeptide epoxyketone. It is FDA approved as a single agent or in combination with dexamethasone or lenalidomide plus dexametha- sone for the treatment of patients with relapsed or refractory MM who have received at least one prior therapy. Frequent adverse effects (>20% of patients) include anemia, thrombocytopenia, diarrhea, dyspnea, and peripheral edema. There is a risk for cardiac, renal, pulmonary, and hepatic toxicity as well as hypertension.

**Ixazomib** is an orally bioavailable second-generation peptide analogue proteasome inhibitor that interacts with subunit beta type 5 (PSMB5) of the 20S proteasome complex. Ixazomib has an elimination half-life of 9.5 days and is approved for use in combination with lenalidomide and dexamethasone for the treatment of patients with MM after at least one prior therapy (Moreau et al., 2016). Ixazomib can cause diarrhea, peripheral neuropathy, and hepatotoxicity.

**Omacetaxine.** This agent’s mechanisms of action include inhibition of protein translation by preventing the initial elongation step of protein synthesis, thereby depleting the cell of short-lived proteins. Omacetaxine is FDA approved for the treatment of patients with chronic or accelerated phase CML with resistance or intolerance to two or more TKIs.

**CD20 Inhibitors**

CD20 is a cell surface antigen expressed on the surface of all B cells beginning with the pro–B cell stage through its terminal differentiation to plasma cells (see Chapters 34 and 35) and is expressed on about 90% of B-cell neoplasms.

**Rituximab**

Rituximab is a chimeric murine/human monoclonal IgG1 antibody that targets the CD20 B-cell surface antigen. On binding to CD20, rituximab mediates B-cell lysis through CDC and ADCC. In patients with NHL, administration of rituximab depletes circulating and tissue-based B cells within the first 3 weeks, with sustained depletion for 6 to 9 months post-treatment in a majority of patients. Median B-cell levels return to normal by 12 months.

**ADME**

The drug is administered by intravenous infusion both as a single agent and in combination with chemotherapy. Rituximab has a t₁/₂ of about 22 days. As a single agent, it is given weekly for 4 weeks, with maintenance dosing every 3–6 months. In combination regimens, the drug may be administered every 3–4 weeks, with chemotherapy, for up to eight doses. The rate of infusion should be increased slowly to prevent serious hypersensitivity reactions. Pretreatment with antihistamines, acetaminophen, and glucocorticoids decreases the risk of hypersensitivity reactions. Patients with large numbers of circulating tumor cells (as in CLL) are at increased risk for tumor lysis syndrome; in these patients, the initial dose should be no more than 50 mg/m² on day 1 of treatment, and patients should receive standard tumor lysis prophylaxis.

**Therapeutic Uses**

Rituximab is approved as a single agent for relapsed indolent lymphomas and significantly enhances response and survival in combination with
chemotherapy for the initial treatment of diffuse large BCL. Rituximab improves response rates when added to combination chemotherapy for other indolent B-cell NHLs, including CLL, MCL, WM, and marginal zone lymphomas. Maintenance of remission with rituximab delays time to progression and improves overall survival in indolent NHL. It is increasingly used for treatment of autoimmune diseases such as rheumatological disease, thrombotic thrombocytopenic purpura, autoimmune hemolytic anemias, cryoglobulin-induced renal disease, and multiple sclerosis.

**Resistance and Adverse Effects**

Resistance to rituximab may emerge through downregulation of CD20, impaired antibody-dependent cellular cytotoxicity, decreased complement activation, limited effects on signaling and induction of apoptosis, and inadequate blood levels. Polymorphisms in two of the receptors for the antibody Fc region responsible for complement activation may predict the clinical response to rituximab monotherapy in patients with follicular lymphoma but not in CLL. Rituximab infusion reactions can be life-threatening, but with pretreatment, reactions are usually mild and limited to fever, chills, throat itching, urticaria, and mild hypotension. All respond to decreased infusion rates and antihistamines. Uncommonly, patients may develop severe mucocutaneous skin reactions, including Stevens-Johnson syndrome. Rituximab may cause reactivation of hepatitis B virus or rarely, JC virus (with progressive multifocal leukoencephalopathy). Hypogammaglobulinemia and autoimmune syndromes (idiopathic thrombocytopenic purpura, thrombotic thrombocytopenic purpura, autoimmune hemolytic anemia, pure red cell aplasia, and delayed neutropenia) may supervene 1–5 months after administration.

**Ofatumumab**

Ofatumumab is a second monoclonal antibody that binds to CD20 at sites on the major and minor extracellular loops of CD20, distinct from the site targeted by rituximab. Antibody binding results in B-cell lysis via CDC and ADCC. Ofatumumab is approved for treating patients with CLL after failure of fludarabine and alemtuzumab. A complex dosing scheme is used, beginning with small (300-mg) doses on day 1, followed by higher doses (up to 2 g/week) later. Ofatumumab’s primary toxicities consist of immunosuppression and opportunistic infection, hypersensitivity reactions during antibody infusion, and myelosuppression. Blood counts should be monitored during treatment. Rarely, patients may develop reactivation of viral infections. The drug should not be administered to patients with active hepatitis B infection; liver function should be monitored in hepatitis B carriers.

**Obinutuzumab**

Obinutuzumab is a humanized monoclonal IgG1 antibody that recognizes the CD20 antigen expressed on the surface of B cells. On binding to CD20, obinutuzumab mediates B-cell lysis through CDC and ADCC. Obinutuzumab is approved for the treatment of treatment-naïve patients with CLL in combination with chemotherapy. Patients who receive this combination therapy are more likely to go into complete remission and have better overall survival than those receiving chlorambucil alone. In this study, they also compared patients treated with obinutuzumab and chlorambucil to patients who were treated with rituximab and chlorambucil. A comparison of patients with CLL given obinutuzumab–chlorambucil combination therapy versus rituximab–chlorambucil combination therapy showed that the obinutuzumab–chlorambucil combination provided higher rates of complete remission as well as longer progression-free survival. Cytopenias, fever, cough, and musculoskeletal disorders are frequent side effects.

**Other Cell Surface Targets for Monoclonal Antibodies**

**Alemtuzumab**

Alemtuzumab is a humanized IgGκ monoclonal antibody that binds to CD52 antigen. CD52 is found on the surface of a subset of normal neutrophils and on all B and T lymphocytes, on testicular elements and sperm, and on most BCLs and T-cell lymphomas. Consistently high levels of CD52 expression on lymphoid tumor cells and the lack of CD52 modulation with antibody binding make this antigen a potential target for unconjugated monoclonal antibodies. Alemtuzumab can induce tumor cell death through ADCC and CDC.

**Resistance and Adverse Effects**

Resistance to alemtuzumab is administered intravenously in dosages of 30 mg/d three times/week. Premedication with diphenhydramine and acetaminophen should precede drug infusion. Dosing should begin with a low-dose infusion, followed by an increased dose 2 days later and, if well tolerated, the highest dose 2 days later. The drug has an initial mean t1/2 of 1 h, but after multiple doses, the t1/2 extends to 12 days, and steady-state plasma levels are reached at approximately week 6 of treatment.

**Therapeutic Uses**

Alemtuzumab is approved as a single agent for the treatment of B-cell CLL. Clinical activity had been demonstrated in both B- and T-cell low-grade lymphomas and CLL, including patients with disease refractory to purine analogues. In chemotherapy-refractory CLL, overall response rates are about 40%, with complete responses of 6% in multiple series. Response rates in treatment-naïve patients with CLL are higher (overall response rates of 83% and complete responses of 24%). Alemtuzumab is also approved for the treatment of patients with relapsing forms of multiple sclerosis under a different label.

**Adverse Effects**

Serious toxicities include acute infusion reactions and depletion of normal neutrophils and T cells. Myelosuppression, with depletion of all blood lineages, occurs in the majority of patients and may represent either direct marrow toxicity or autoimmune responses. Immunosuppression leads to a significant risk of fungal, viral, and other opportunistic infections, particularly in patients who have previously received purine analogues. Patients should receive prophylaxis against Pneumocystis carinii and herpesvirus during treatment and for at least 2 months following therapy with alemtuzumab. Because reactivation of cytomegalovirus (CMV) infections may follow antibody use, patients should be monitored for symptoms and signs of viremia, hepatitis, and pneumonia. CD4+ T-cell counts may remain profoundly depleted (<200 cells/μL) for 1 year.

**Dinutuximab**

Dinutuximab is a monoclonal antibody that targets glycolipid GD2, expressed on neuroblastoma cells and on normal cells of neuroectodermal origin, including the CNS and peripheral nerves. It is approved in combination with GM-CSF, IL-2, and RA for high-risk neuroblastoma in pediatric patients. Dinutuximab can cause nerve damage and life-threatening infusion reactions.

**Daratumumab**

Daratumumab is a human IgG1 monoclonal antibody that binds to CD38 and inhibits the growth of CD38-expressing tumor cells by inducing immune-mediated tumor cell lysis through CDC and ADCC. The FDA has recently approved daratumumab for treatment of patients with MM in combination with lenalidomide or bortezomib and dexamethasone. The most frequent adverse effects are infusion reactions, neutropenia, thrombocytopenia, fatigue, nausea, diarrhea, muscle spasms, back pain, pyrexia, cough, dyspnea, peripheral edema, peripheral sensory neuropathy, and upper respiratory tract infection.

**Elotuzumab**

Elotuzumab is a humanized monoclonal IgGκ antibody that targets SLAMF7 (CD319). It is approved for the treatment of patients with MM who have received one to three prior therapies. Binding of elotuzumab to the antigen on myeloma cells induces ADCC-dependent tumor cell lysis. ADCC is enhanced by stimulation of the SLAMF7 pathway in NK cells by elotuzumab.
**Blinatumomab**

Blinatumomab is a bisppecific antibody that recognizes sites on the surfaces of B cells and T cells, thereby enabling a patient’s T cells to recognize malignant B cells. Blinatumomab binds simultaneously to CD3 (part of the TCR) on T cells and to CD19 on B cells. The drug links these two cell types and activates the T cell to exert cytotoxic activity on CD19* target B cells. Blinatumomab is approved for the treatment of Philadelphia chromosome-negative relapsed or refractory B-cell precursor ALL. Major adverse effects are cytokine release syndrome, neurologic toxicities, neutropenic fever, and sepsis.

**Monoclonal Antibody–Cytotoxin Conjugates**

**Gemtuzumab Ozogamicin**

**Mechanism of Action**

Gemtuzumab ozogamicin is a humanized monoclonal antibody against CD33 covalently linked to a semisynthetic derivative of calicheamicin, a potent antitumor antibiotic. The CD33 antigen is present on most hematopoietic cells, on more than 80% of AMLs, and on most myeloid cells in patients with MDSs. However, other normal cell types lack CD33 expression, making this antigen attractive for targeted therapy. CD33 has no known biological function, although monoclonal antibody cross-linking inhibits normal and myeloid leukemia cell proliferation. Following its binding to CD33, gemtuzumab ozogamicin undergoes endocytosis; cleavage of calicheamicin from the antibody takes place within the lysosome. The potent toxin then enters the nucleus, binds in the minor groove of DNA, and causes double-strand DNA breaks and cell death.

**ADME**

The antibody conjugate produces a 30% complete response rate in relapsed AML when administered at a dose of 9 mg/m² for up to three doses at 2-week intervals. The $t_{1/2}$ of total and unconjugated calicheamicin are 41 and 143 h, respectively. Following a second dose, the $t_{1/2}$ of drug-antibody conjugate increases to 64 h. Most patients require two to three doses to achieve remission.

**Therapeutic Use**

The drug was initially approved for use in patients more than 60 years of age with AML in first relapse. However, the drug is not yet available, pending clinical trials to more precisely define a population with high likelihood of efficacy. Primary toxicities include myelosuppression in all patients treated and hepatocellular damage in 30%–40% of patients, manifested by hyperbilirubinemia and enzyme elevations. This agent also causes a syndrome that resembles hepatic veno-occlusive disease when patients subsequently undergo myeloablative therapy or when gemtuzumab ozogamicin follows high-dose chemotherapy.

**Brentuximab Vedotin**

Brentuximab vedotin is an anti-CD30 IgG1 monoclonal antibody linked via a proteolytic cleavage. MMAE disrupts the microtubule network, inducing mitotic arrest, disruption of intracellular trafficking, and apoptosis. The adverse effects of treatment include cardiac dysfunction as described for unconjugated trastuzumab. Hepatotoxicity is an additional risk.

**Denileukin Diftitox**

Denileukin diftitox is an immunotoxin made from the genetic recombination of IL-2 and the catalytically active fragment of diphteria toxin. The high-affinity IL-2R has limited tissue expression and is an attractive target for an immunotoxin. Introduction of the diphtheria toxin fragment into cells leads to ADP-riboosylation and inactivation of eukaryotic elongation factor EF-2, inhibition of protein synthesis, and thence cell death.

**ADME**

Denileukin diftitox is administered by intravenous infusion over 30–60 min for 5 consecutive days every 21 days for eight cycles. The drug is quickly distributed and has a terminal $t_{1/2}$ of about 70 min. Denileukin diftitox clearance in later cycles of treatment accelerates by 2- to 3-fold as a result of development of antibodies, but serum levels exceed those required to produce cell death in IL-2R-expressing cell lines (1–10 ng/mL for $> 90$ min).

**Therapeutic Uses**

Denileukin diftitox is approved for the treatment of recurrent/refractory cutaneous T-cell lymphomas. Response rates of 30%–37% have been achieved, with a median response duration of 6.9 months. Patients with a history of hypersensitivity reactions to diphtheria toxin or IL-2 should not be treated. Significant toxicities include acute hypersensitivity reactions, a vascular leak syndrome, and constitutional toxicities; glucocorticoid premedication significantly decreases toxicity.

**Radioimmunoconjugates**

Radioimmunoconjugates provide targeted delivery of radionuclides to tumor cells. Iodine (131I) is a favored radioisotope because it is readily available, relatively inexpensive, and easily conjugated to a monoclonal antibody. The γ particles emitted by 131I can be used for both imaging and therapy, but protein-iodine conjugates have the drawback of releasing free 131I and 131I-tyrosine into the blood and thus present a health hazard to people in contact with the patient. The β-emitter 90Y (yttrium) has emerged as an alternative to 131I, based on its higher energy and longer path length. Thus, it may be more effective in tumors with larger diameters. It also has a short $t_{1/2}$ and remains conjugated, even after endocytosis, providing a safer profile for outpatient use. Currently available radioimmunoconjugates consist of murine monoclonal antibodies against CD20 conjugated with 131I (tositumomab) or 90Y (ibritumomab). Both drugs have shown responses rates in relapsed lymphoma of 65%–80%. Adverse effects include antibody-related hypersensitivity, bone marrow suppression, and secondary leukemias. Both radioimmunoconjugates targeting CD20 on lymphomas have been approved; concerns over toxicity have limited their use.

**Cytokines and Growth Factors**

**Colony-Stimulating Factors**

Many agents used for cancer chemotherapy suppress the production of multiple types of hematopoietic cells, and bone marrow suppression can limit the delivery of chemotherapy on schedule and at prescribed doses. The availability of recombinant growth factors for erythrocytes (i.e., erythropoietin), granulocytes (i.e., G-CSF), and granulocytes and macrophages (i.e., GM-CSF) has advanced the ability to use combination therapy or high-dose cytotoxic therapy with diminished complications such as febrile neutropenia (see Chapter 66). Chapter 41 presents the basic pharmacology of hematopoietic growth factors.
**Inhibitors of Histone Deacetylase**

Histone deacetylases are a class of enzymes that catalyze the removal of acetyl groups from acetylated lysine amino acids in histones, thereby altering the transcriptional activation of cellular genes. Thus, HDAC inhibitors produce a broad spectrum of epigenetic effects. HDACs can also deacetylate other proteins, including transcription factors. Overexpression of HDACs found in some cancers, or aberrant recruitment of HDACs to oncogenic transcription factors, can cause hypoacetylation of core nucleosomal histones. This hypoacetylation results in a condensed chromatin structure and repression of gene transcription. In contrast, inhibition of HDAC activity leads to the accumulation of acetyl groups on the histone lysine residues, an open chromatin structure, and activation of target genes that are selectively repressed in tumors. The result of HDAC inhibition can be differentiation with the emergence of a more normal cellular phenotype or cell cycle arrest with expression of endogenous regulators of cell cycle progression. Due to the diversity of the HDAC family of enzymes and their tissue distribution, HDAC inhibitors with different selectivity can induce a wide variety of cellular effects.

**Panobinostat**

Panobinostat is an orally bioavailable, nonselective pan-HDAC inhibitor. The inhibitory activity leads to apoptosis of malignant cells via multiple pathways. Panobinostat is approved for the treatment of patients with MM who have received at least two previous treatments, including bortezomib and an immunomodulatory agent.

**ADME**

The oral bioavailability is about 21%. Panobinostat is metabolized through CYP3A. It is recommended to avoid concomitant use with strong CYP3A4 inducers or inhibitors. Otherwise, dose adjustments will be necessary. The elimination half-life is approximately 37 h.

**Adverse Effects**

The most common adverse effects are diarrhea (severe in 25% of patients), fatigue, nausea, peripheral edema, decreased appetite, pyrexia, and vomiting. The most common nonhematologic laboratory abnormalities (incidence ≥ 40%) are hypophosphatemia, hypokalemia, hyponatremia, and increased creatinine. The common hematologic laboratory abnormalities (incidence ≥ 60%) are thrombocytopenia, lymphopenia, leukopenia, neutropenia, and anemia. Fatal cardiac ischemic events, severe arrhythmias, and ECG changes have occurred in patients receiving panobinostat. Arrhythmias may be exacerbated by electrolyte abnormalities. Avoid concomitant use of antiarrhythmic or QT-prolonging drugs. Close cardiac monitoring during treatment is recommended.

**Romidepsin**

Romidepsin is an HDAC inhibitor used in the treatment of cutaneous and peripheral T-cell lymphoma. Romidepsin is a natural product obtained from the bacteria *Chromobacterium violaceum* and is sometimes referred to as depsipeptide. Romidepsin functions as a prodrug. Within cells, a zinc-binding thiol of the drug is reduced and interacts with a zinc atom in the binding pocket of HDAC to block its activity.

**ADME**

After intravenous administration, the major metabolism is through CYP3A4. Thus, it is recommended to monitor for toxicities related to increased romidepsin exposure when coadministering strong CYP3A4 inhibitors. Avoid use with rifampin and other strong CYP3A4 inducers. The terminal half-life is about 3 h.

**Adverse Effects**

The most commonly observed are nausea and vomiting, anemia, thrombocytopenia, and leukopenia as well as abnormal electrolyte levels and ECG changes.

**Vorinostat**

Vorinostat is a small-molecule, orally bioavailable HDAC inhibitor; it is also known as SAHA based on its chemical name suberanilhydroxamic acid.

**Mechanism of Action**

Vorinostat binds to the active site of HDACs and chelates zinc ions in the active site. The resulting inhibition of HDACs causes the accumulation of acetylated histones and other acetylated proteins, amongst which are transcription factors crucial for cell differentiation. Vorinostat inhibits the enzymatic activities of HDAC1, 2, 3 (class I) and HDAC6 (class II) at nanomolar concentrations (IC$_{50}$ < 100 nM). In vitro, vorinostat induces cell cycle arrest or apoptosis of some cancer cells.

**ADME**

The absorption of vorinostat is slightly improved when taken with a meal. Metabolism is mostly through glucuronidation and hydrolysis. The elimination t$_{1/2}$ is about 2 h.

**Therapeutic Use; Adverse Effects**

Vorinostat is approved for the treatment of patients with cutaneous T-cell lymphoma with persistent or recurrent disease after two systemic therapies. The most common adverse reactions are diarrhea, fatigue, nausea, thrombocytopenia, anorexia, and dysgeusia. Patients with severe hepatic impairment should be excluded from treatment. Vorinostat is classified as pregnancy category D: evidence of risk.

**Acknowledgment:** Bruce A. Chabner, Jeffrey Barnes, Joel Neal, Erin Olson, Hamza Mujagic, Lecia Sequist, Wynham Wilson, Dan L. Longo, Constantine Mitsiades, and Paul Richardson contributed to this chapter in the recent edition of this book. We have retained some of their text in the current edition.

Note: CYP3A4 substrate: For drugs that are subject to hepatic metabolism by CYP enzymes, drug exposure of a patient can be affected by coadministration of inhibitors or inducers of CYP3A4 and can then reduce efficacy or increase side effects.

Embryo-fetal toxicity: Consider that all of these drugs can cause fetal harm. Advise women of the potential risk to a fetus and to avoid pregnancy while taking the drug and for 1 month after cessation of therapy. Advise men to avoid fathering a child during the same time period. Avoid lactation during therapies.

DRUGS THAT TARGET THE GLUCOCORTICOID RECEPTOR

ESTROGENS AND ANDROGENS IN CANCER
- Hormone Therapy of Breast Cancer
- Hormone Therapy of Prostate Cancer

A Note on Treatment Regimens
Cancer treatment regimens change to reflect continuous advances in basic and clinical science: new drugs, both small molecules and biologicals; improved methods of targeting and timing of drug delivery; agents with altered pharmacokinetic properties and selectivities; the use of rational multidrug combinations; and greater knowledge of the basic cell biology of tumorigenesis, metastasis, and immune function, amongst other advances. As a consequence, this chapter presents relatively few detailed treatment regimens; rather, we refer the reader to the web-based resources of the U.S. FDA and the NCCN. Table 67–1 provides the details and demonstrates the complexities of treatment of two cancers.

The growth of a number of cancers is hormone dependent or regulated by hormones. Glucocorticoids are used for their antiproliferative and lympholytic properties and to ameliorate untoward responses to other treatments. Estrogen and androgen antagonists, steroid synthesis inhibitors, and GnRH analogues and antagonists are all effective in extending survival and delaying or preventing tumor recurrence of both breast and prostate cancer. These molecules interrupt the stimulatory axis created by hormones. Glucocorticoids are used for their antiproliferative and apoptotic responses in sensitive cells. The pharmacology, major therapeutic uses, and toxic effects of the glucocorticoids are discussed in Chapter 46. Only the applications of these drugs in the treatment of neoplastic disease are considered here.

Glucocorticoids act by binding to a specific GR that is a member of the nuclear receptor family of transcription factors. The GR translocates to the nucleus and induces complex gene expression changes (Chapter 46) that lead to antiproliferative and apoptotic responses in sensitive cells. Because of their lympholytic effects and their ability to suppress mitosis in lymphocytes, glucocorticoids are used as cytotoxic agents in the treatment of acute leukemia in children and malignant lymphoma in children and adults. In acute lymphoblastic or undifferentiated leukemia of childhood, glucocorticoids may produce prompt clinical improvement and objective hematological remissions in 30% of children. However, the duration of remission is brief. Remissions occur more rapidly with glucocorticoids than with antimitabolites, and there is no evidence of cross-resistance to unrelated agents. Thus, therapy is initiated with prednisone and vincristine, often followed by an anthracycline or methotrexate, and L-asparaginase. Glucocorticoids are a valuable component of curative regimens for other lymphoid malignancies, including Hodgkin disease, non-Hodgkin lymphoma, multiple myeloma, and CLL. Glucocorticoids are extremely helpful in controlling autoimmune hemolytic anemia and thrombocytopenia associated with CLL.

A number of glucocorticoids are available and at equivalent dosages exert similar effects (see Chapter 46). Prednisone, for example, usually is administered orally in doses up to 100 mg for the first few days and gradually reduced to the lowest possible effective dose. Side effects of these agents include glucose intolerance, immunosuppression, osteoporosis, and psychosis (see Chapter 46). Dexamethasone is one of the preferred agents for remission induction in multiple myeloma, typically in combination with bortezomib, anthracyclines, or lenalidomide. Glucocorticoids, particularly dexamethasone, are used in conjunction with radiotherapy to reduce edema related to tumors in critical areas such as the superior mediastinum, brain, and spinal cord. Frequent lower doses (4–6 mg every 6 h) can have dramatic effects in restoring neurological function in patients with cerebral metastases, but these effects are temporary. However, acute changes in dexamethasone dosage can lead to a rapid recrudescence of symptoms. Dexamethasone should not be discontinued abruptly in patients receiving radiotherapy or chemotherapy for brain metastases. Dexamethasone is also frequently used as part of an antiemetic regimen in patients receiving chemotherapy.

Estrogens and Androgens in Cancer
The pharmacology of the estrogens and androgens is described in detail in Chapters 44 and 45. These agents are of value in certain cancers, most notably those of the prostate and breast, because these organs are dependent on hormones for their growth, function, and morphological integrity.

Hormone Therapy of Breast Cancer
Historically, high doses of estrogen have been recognized as effective treatment of breast cancer. More recent studies have suggested lower doses of estrogen can be effective in the management of endocrine-resistant disease (Ellis et al., 2009). The growth inhibitory effect of estrogens may be related to their ability to induce apoptosis in endocrine-resistant breast cancer (Jordan, 2015; Song and Santen, 2003). However, interruption of estrogen-induced signaling with antiestrogens such as tamoxifen and drugs that reduce estrogen production such as AIs and GnRH analogues have been found to be more effective and better tolerated. These drugs have largely replaced estrogens or androgens for the treatment of breast cancer.

The presence of the ER and PR in breast cancer tissue identifies the subset of hormone-receptor-positive (HR+) patients with a more than 60% likelihood of responding to hormonal therapy. The response rate to antiestrogen treatment is somewhat lower in the subset of patients with tumors that are ER- or PR- but also positive for human epidermal growth factor receptor HER2/neu amplification. In contrast, ER-negative and...
PR-negative carcinomas do not respond to hormonal therapy. In patients with metastatic cancer, responses to hormonal therapy may not be apparent clinically or by imaging for 8–12 weeks. The medication typically should be continued until the disease progresses or unwanted toxicities develop.

Antiestrogen approaches for the therapy of HR+ breast cancer include the use of SERMs, SERDs, and AIs (Table 68–1).

### Drugs That Target the Estrogen Receptor

**Selective Estrogen Receptor Modulators.** The SERMs bind to the ER and exert either estrogenic or antiestrogenic effects, depending on the specific organ (Chapter 44). Tamoxifen is the most widely studied estrogenic drug used in the treatment of breast cancer. Tamoxifen also exerts estrogenic agonist effects on nonbreast tissues, which influences the overall therapeutic index of the drug. Therefore, several novel antiestrogen compounds that offer the potential for enhanced efficacy and reduced toxicity compared with tamoxifen have been developed. These novel antiestrogens can be divided into tamoxifen analogues (e.g., toremifene, droloxifene, idoxifene); “fixed-ring” compounds (e.g., raloxifene, bazedoxifene); “flexible” compounds (e.g., raloxifene, bazedoxifene, lasofoxifene, miroxifene, levormeloxifene); and the SERDs (e.g., fulvestrant), the latter also termed “pure antiestrogens” (Howell et al., 2004; McDonnell and Wardell, 2010).

**Tamoxifen.** Tamoxifen was developed as an oral contraceptive but instead was found to induce ovulation and to have antiproliferative effects on estrogen-dependent breast cancer cell lines (Jordán, 2006). Tamoxifen is prescribed for the adjuvant therapy of early-stage breast cancer (Early Breast Cancer Trialists’ Collaborative Group, 2011) and for the therapy of advanced breast cancer (Burstein et al., 2010). Tamoxifen and other SERMs such as raloxifene are also used for the prevention of breast cancer in high-risk patients such as those with a strong family history or prior nonmalignant breast pathology (Visvanathan et al., 2013). The uses, pharmacology, and mechanism of action of raloxifene are discussed in Chapter 44.

- **Mechanism of Action.** Tamoxifen is a competitive inhibitor of estrogens (e.g., 17β-estradiol), binding to the ER, and antagonizes estrogen-induced proliferation of human breast cancer. There are two subtypes of ERs: ERα and ERβ, which have different tissue distributions and can either homo- or heterodimerize. Binding of estrogen and SERMs to the estrogen-binding sites of the ERs initiates a change in conformation of the ER, dissociation of the ER from heat-shock proteins, and ER dimerization. Dimerization facilitates the binding of the ER to specific DNA EREs in the vicinity of estrogen-regulated genes. Coregulator proteins interact with the liganded receptor to act as coresspressors or coactivators of gene expression (Chapter 44). Elegant studies of the crystal structure of ERα bound to different ligands indicate that, when an ER agonist is bound to the ligand-binding domain of the ER, helix 12 enables recruitment of coactivators. Conversely, with an estrogen antagonist such as 4-hydroxytamoxifen bound to the ER, helix 12 is displaced, the binding of coactivators is disrupted, and subsequent estrogen-induced gene transcription is inhibited (Nettles and Greene, 2005). Differences in tissue distribution of the ER subtypes and the function and relative amounts of different transcriptional coregulator proteins likely explains the antagonist response to tamoxifen in ER+ breast cancer and partial agonist activities in noncancerous organs. Organs displaying agonist effects of tamoxifen include the uterine endometrium (endometrial hyperplasia, vaginal bleeding, and endometrial cancer); the coagulation system (thromboembolism); bone metabolism (increase in bone mineral density, which can slow development of osteoporosis); and liver (tamoxifen lowers total serum cholesterol, low-density lipoprotein cholesterol, and lipoproteins and raises apolipoprotein A-I levels).

- **ADME.** Tamoxifen is readily absorbed following oral administration, with peak concentrations measurable after 3–7 h and steady-state levels reached at 4–6 weeks. Metabolism of tamoxifen is complex and primarily involves CYPs 3A4/5, and 2D6 in the formation of N-desmethyl tamoxifen and CYP2D6 to form 4-hydroxytamoxifen, a more potent metabolite (Figure 68–1). Both metabolites can be further converted to 4-hydroxy-N-desmethyltamoxifen (endoxifen), which retains high affinity for the ER. The parent drug has a terminal t1/2 of 7 days. After enterohepatic circulation, glucuronides and other metabolites are excreted in the stool; excretion in the urine is minimal. Polymorphisms in CYP2D6 that reduce its activity lead to lower plasma levels of the potent metabolite 4-OH tamoxifen and endoxifen, but whether this leads to inferior efficacy of tamoxifen treatment and higher risks of disease relapse is unclear (Hertz and Rae, 2016). While drugs that inhibit CYP2D6 activity, such as antidepressants, have been postulated to minimize tamoxifen activity in breast cancer, more recent studies do not suggest a clinically significant impact (Haque et al., 2016).

- **Therapeutic Uses.** Tamoxifen is given orally once per day. Tamoxifen is used for the treatment of women with ER+ metastatic breast cancer following primary excision of an ER+ tumor as an adjuvant treatment to prevent recurrence and extend overall survival. For the adjuvant treatment of premenopausal women, tamoxifen is given for at least 5 years (Table 68–1). Tamoxifen may also be used for postmenopausal women, but AIs are preferred as they are associated with further reductions in the risk of recurrence (Early Breast Cancer Trialists’ Collaborative Group, 2015). Recent studies indicated that patients with breast cancer derive modest additional benefit, in terms of disease-free survival, overall survival, and decrease in contralateral breast cancer risk, if tamoxifen is taken for up to 10 years or AIs are continued for 5–10 years after completion of 5 years of tamoxifen (Davies et al., 2013; Goss et al., 2016). Of note, while taken for a finite time, tamoxifen has been shown to have persisting long-term benefits (Ekhholm et al., 2016). Tamoxifen may be taken as sole adjuvant therapy or after adjuvant chemotherapy (Table 68–1). Alternative or additional antiestrogen strategies in the adjuvant treatment of premenopausal women with ER+ breast cancer include oophorectomy or...
suppression of ovarian function with GnRH analogues (Table 68–2) typically given in combination with either tamoxifen or an AI. These combinations used in premenopausal women further reduce estrogen stimulation of breast cancer and result in lower rates of disease recurrence in very young women and in patients receiving chemotherapy (Francis et al., 2015). Some studies suggested improved response rates with these combinations in patients with metastatic disease. Tamoxifen also has shown effectiveness (a 40%–50% reduction in tumor incidence) in preventing breast cancer in women at increased risk (Fisher et al., 1998). In the preventive setting, tamoxifen reduces

only ER⁺ tumors, not ER-negative tumors, and does not affect overall mortality.

• Toxicity. The common adverse reactions to tamoxifen include vasomotor symptoms (hot flashes), atrophy of the lining of the vagina, menstrual irregularities, vaginal bleeding and discharge, and pruritus vulvae and occur with increasing severity in postmenopausal women. Because of partial agonist activity, tamoxifen also increases the incidence of endometrial cancer by 2- to 3-fold, particularly in postmenopausal women who receive tamoxifen for more than 2 years. Tamoxifen slightly increases the risk of thromboembolic events, which increase with the age of a patient and also in the perioperative period. Hence, it is often advisable to temporarily halt tamoxifen prior to elective surgery. Tamoxifen can cause retinal deposits, decreased visual acuity, and cataracts, although these changes are uncommon.

• Endocrine Resistance. Initial or acquired resistance to endocrine therapies (tamoxifen or AIs) frequently occurs (Moy and Goss, 2006). Multiple mechanisms contribute to endocrine resistance in breast cancer (Clarke et al., 2015); these mechanisms include loss of ER expression, activation of ER independent pathways, and hormone-independent activation of the ER by stress kinase or growth factor–activated cellular kinase pathways. In particular, cross talk between the ER and the HER2/neu pathway has been implicated in tamoxifen resistance. In a significant portion of metastatic breast cancers, estrogen-deprivation therapy can lead to selection of cancer cells expressing an ER with mutations that allow hormone-independent activation. Acquired ER mutations also contribute to estrogen-resistant breast cancer growth (Jeselsohn et al., 2015).

Toremifene. Toremifene is a triphenylethylene derivative of tamoxifen and has a similar pharmacological profile, clinical efficacy, and safety (Howell et al., 2004). Toremifene is used occasionally in the metastatic setting for the treatment of breast cancer in women with tumors that are ER⁺ or of unknown receptor status. In rare cases, toremifene can cause heart rhythm problems through prolongation of the QT interval.

Selective Estrogen Receptor Downregulators. The SERDS, also termed pure antiestrogens, include fulvestrant and a number of agents in experimental trials. SERDs, unlike SERMs, are devoid of any estrogen agonist activity.

Fulvestrant. Fulvestrant is currently the only FDA-approved SERD, either as a single agent or in combination with palbociclib, a CDK4/6 inhibitor (Chapter 67), for postmenopausal women with HR⁺ metastatic breast cancer that has progressed on antiestrogen therapy.

Mechanism of Action. Fulvestrant is a steroidal antiestrogen that binds to the ER with an affinity more than 100 times that of tamoxifen. The drug not only inhibits the binding of estrogen but also alters the receptor structure such that the receptor is targeted for proteasomal degradation; fulvestrant also may inhibit receptor dimerization. Unlike tamoxifen, which stabilizes or even increases ER expression, fulvestrant reduces the number of ER molecules in cells; as a consequence of this ER downregulation, the drug abolishes ER-mediated transcription of estrogen-dependent genes.

ADME. Fulvestrant is given intramuscularly with initial biweekly loading doses in the first month followed by once monthly injections thereafter. Using this dosing regimen, steady-state levels are achieved within the first month (Robertson et al., 2014) (Table 68–1). Peak plasma concentrations are reached about 7 days after intramuscular administration of fulvestrant and the plasma t½ is about 40 days. There is rapid distribution and extensive protein binding of this highly lipophilic drug. Various pathways, similar to those of steroid metabolism (oxidation, aromatic hydroxylation, and conjugation), metabolize fulvestrant. CYP3A4 appears to be the major CYP isoenzyme involved in the metabolism of fulvestrant. The putative metabolites possess no estrogenic activity, and only the 17-keto compound demonstrates a level of antiestrogenic activity (~22% that of fulvestrant). Less than 1% of the parent drug is excreted intact in the urine.

Therapeutic Uses. Fulvestrant is used in postmenopausal women as antiestrogen therapy of HR⁺ metastatic breast cancer after progression on first-line antiestrogen therapy such as tamoxifen or an AI. Fulvestrant is at least as effective in this setting as the third-generation AI anastrozole. Recently, the addition of a CDK4/6 inhibitor (Chapter 67) to fulvestrant...
Drugs That Decrease Estrogen Levels

Aromatase Inhibitors. Aromatase converts androgens to estrogens (e.g., androstenedione to estrone). AIs (Figure 68–2) block this enzymatic activity, thereby reducing estrogen production (Figure 67–3). AIs are now considered the standard of care for adjuvant treatment of postmenopausal women with ER+ breast cancer, either as initial therapy or after tamoxifen. (Dowsett et al., 2010). AIs are also approved in the initial treatment of metastatic HR+ breast cancer, often in combination with CDK4/6 inhibitors, and for disease that has progressed following tamoxifen treatment in postmenopausal women.

Aromatase (CYP19A1) is responsible for the conversion of adrenal androgens and gonadal androstenedione and testosterone to the estrogens estrone (E1) and estradiol (E2), respectively (Figure 68–2; reactions catalyzed by aromatase are noted by a green A beside the reaction arrow). In postmenopausal women, this conversion occurs in nonovarian tissues (fat, liver, muscle, brain, breast, and breast tumors) and is the primary source of circulating estrogens. In premenopausal women, estrogen is primarily produced in the ovaries. AIs increase gonadotropin production in premenopausal women, which reduces their ability to inhibit ovarian estrogen production. As a result, AIs are not effective in premenopausal women without additional ovarian suppression (e.g., with GnRH analogues; see the next section and Table 68–2). In postmenopausal women, AIs suppress most peripheral aromatase activity, leading to profound estrogen deprivation. AIs are classified as first, second, or third-generation inhibitors (e.g., aminoglutethimide, formestane) AIs are no longer used for breast cancer treatment because of their side effects. Third-generation inhibitors include the type 1 steroidal agent exemestane and the type 2 nonsteroidal imidazoles anastrozole and letrozole; they are approved for use in postmenopausal women (Brodie and Njar, 2000). Third-generation AIs are used as part of the treatment of early-stage and advanced breast cancer in postmenopausal women and for chemoprevention (Table 68–1). The type 1 and 2 AIs have similar clinical efficacy and toxicity profiles (Goss et al., 2013), and these are summarized for AIs using anastrozole as a prototype. For letrozole and exemestane, additional drug-specific information is given.

- **Anastrozole.** Anastrozole is a potent and selective triazole AI. Anastrozole, like letrozole, binds competitively and specifically to the heme group of the enzyme. Thus, they commonly are known as aromatase inactivators. Type 2 inhibitors are nonsteroidal and bind reversibly to the heme group of the enzyme, producing reversible inhibition.

Third-Generation Aromatase Inhibitors. First- and second-generation (e.g., aminoglutethimide, formestane) AIs are no longer used for breast cancer treatment because of their side effects. Third-generation inhibitors include the type 1 steroidal agent exemestane and the type 2 nonsteroidal imidazoles anastrozole and letrozole; they are approved for use in postmenopausal women (Brodie and Njar, 2000). Third-generation AIs are used as part of the treatment of early-stage and advanced breast cancer in postmenopausal women and for chemoprevention (Table 68–1). The type 1 and 2 AIs have similar clinical efficacy and toxicity profiles (Goss et al., 2013), and these are summarized for AIs using anastrozole as a prototype. For letrozole and exemestane, additional drug-specific information is given.

- **Anastrozole.** Anastrozole is a potent and selective triazole AI. Anastrozole, like letrozole, binds competitively and specifically to the heme group of the enzyme. Thus, they commonly are known as aromatase inactivators. Type 2 inhibitors are nonsteroidal and bind reversibly to the heme group of the enzyme, producing reversible inhibition.

Third-generation inhibitors include the type 1 steroidal agent exemestane and the type 2 nonsteroidal imidazoles anastrozole and letrozole; they are approved for use in postmenopausal women (Brodie and Njar, 2000). Third-generation AIs are used as part of the treatment of early-stage and advanced breast cancer in postmenopausal women and for chemoprevention (Table 68–1). The type 1 and 2 AIs have similar clinical efficacy and toxicity profiles (Goss et al., 2013), and these are summarized for AIs using anastrozole as a prototype. For letrozole and exemestane, additional drug-specific information is given.

- **Anastrozole.** Anastrozole is a potent and selective triazole AI. Anastrozole, like letrozole, binds competitively and specifically to the heme group of the enzyme. Thus, they commonly are known as aromatase inactivators. Type 2 inhibitors are nonsteroidal and bind reversibly to the heme group of the enzyme, producing reversible inhibition.
Figure 68–3  Steroid synthesis pathways. The shaded area contains the pathways used by the adrenal glands and gonads and clinically used agents that inhibit the pathways. Enzymes are labeled in green, inhibitors in red. Pertaining to this figure only, A, aromatase; 3β, 3β-hydroxysteroid dehydrogenase; 5αR, 5α-reductase; 11β, 11β-hydroxylase; 17, 20, C-17, 20-lyase (also CYP17); 17α, 17α-hydroxylase (CYP17); 17βR, 17β-reductase; 18, aldosterone synthase; 21, 21-hydroxylase.

**HORMONES AND RELATED AGENTS IN THE THERAPY OF CANCER**

**Figure 68–3**  Steroid synthesis pathways. The shaded area contains the pathways used by the adrenal glands and gonads and clinically used agents that inhibit the pathways. Enzymes are labeled in green, inhibitors in red. Pertaining to this figure only, A, aromatase; 3β, 3β-hydroxysteroid dehydrogenase; 5αR, 5α-reductase; 11β, 11β-hydroxylase; 17, 20, C-17, 20-lyase (also CYP17); 17α, 17α-hydroxylase (CYP17); 17βR, 17β-reductase; 18, aldosterone synthase; 21, 21-hydroxylase.

**Letrozole.** The clinical uses and side-effect profile of the type 2 AI letrozole are similar to that detailed in the previous section for anastrozole (Table 68–1). Letrozole-specific information is as follows:

**ADME.** Letrozole is rapidly absorbed after oral administration, with a bioavailability of 99.9%. Steady-state plasma concentrations of letrozole are reached after 2–6 weeks of treatment. Following metabolism by CYP2A6 and CYP3A4, letrozole is eliminated as an inactive metabolite mainly via the kidneys and has a t1/2 of about 41 h.

**Therapeutic Uses.** The clinical indications for use of letrozole in breast cancer treatment are the same as for anastrozole (Table 68–1).

In addition, improved progression-free survival is observed when HR+ advanced stage breast cancer is treated with letrozole in combination with a CDK4/6 inhibitor (Chapter 67) (Finn et al., 2015; Hortobagyi et al., 2016).

**Exemestane.** Exemestane is a more potent, orally administered analogue of the natural aromatase substrate androsterone and lowers estrogen levels more effectively than does its predecessor, formestane. Exemestane irreversibly inactivates aromatase and is a “suicide substrate” type 1 inhibitor of aromatase. The clinical uses and side-effect profile of exemestane are similar to that detailed in the section for the AI anastrozole. Exemestane-specific information is as follows:

**ADME.** Orally administered exemestane is rapidly absorbed from the GI tract; its absorption is increased by 40% after a high-fat meal. Exemestane has a terminal t1/2 of about 24 h. It is extensively metabolized in the liver, ultimately to inactive metabolites. One metabolite, 17-hydroxyexemestane, has weak androgenic activity that may contribute to antitumor activity. Although active metabolites are excreted in the urine, no dosage adjustments are recommended in patients with renal dysfunction.

**Therapeutic Uses.** The clinical indications for use of exemestane in breast cancer treatment are the same as for anastrozole (Table 68–1). In addition, the use of the mTOR inhibitor everolimus (Chapter 67) with exemestane has been approved for treatment of advanced-stage breast cancer that has progressed on nonsteroidal type 2 AIs (Yardley et al., 2013).

**GnRH Agonists.** Synthetic GnRH analogues (e.g., triptorelin, goserelin, leuprolide; Table 68–2) have greater receptor affinity and reduced susceptibility to enzymatic degradation than the naturally occurring decapeptide GnRH molecule and are 100-fold more potent GnRH agonists than the native decapeptide. They are used in the adjuvant treatment of breast cancer or metastatic disease for women who have functioning ovaries; typically, they are used in combination with either tamoxifen or AIs. Continuous administration of GnRH agonists downregulates GnRH receptors in the pituitary gland. This suppresses the release of the gonadotropins FSH and LH from the pituitary and prevents follicular maturation.
in the ovary. Serum estrogen levels are reduced to those seen in postmenopausal women or in women after oophorectomy.

**ADME.** GnRH agonists are administered as an injection once a month or every 3 or 6 months. There is in an initial rise in LH and FSH levels, but after 14–21 days of therapy, a sustained decrease in serum LH and estrogen is observed.

**Therapeutic Uses.** In the adjuvant setting, recent studies have demonstrated a benefit for GnRH agonists when given in conjunction with either AIs or tamoxifen in very young or higher-risk premenopausal women (Regan et al., 2016). In addition, these drugs can be given with tamoxifen, AIs, or fulvestrant in premenopausal women with metastatic breast cancer.

**Toxicity.** Side effects are generally related to hypogonadism (i.e., hot flashes, vaginal dryness, decreased libido, osteoporosis, amenorrhea, and dyspareunia). The side effects of GnRH agonists are potentially reversible on cessation of therapy. AI use in premenopausal women combined with ovarian suppression with GnRH analogues increases menopausal symptoms and sexual dysfunction and thus benefits and risks must be carefully considered (Burstein et al., 2016).

**Drugs That Target the Progesterone Receptor**

Progestational agents (see Chapter 44 for details) are mainly used as second agents in hormonal therapy for metastatic hormone-dependent breast cancer and are also used in the management of endometrial carcinoma prior to surgery by surgery and radiotherapy. Progestrone binds to the PR present in target issues, such as breast and the endometrium (Chapter 44). Activation of the PR by progestins in the endometrium is antiproliferative.

**Medroxyprogesterone acetate** is available for oral administration; an alternative oral progestational agent is megestrol acetate. Beneficial effects have been observed in one-third of patients with endometrial cancer. The response of breast cancer to megestrol is predicted by both the presence of HRs (ER and PR) and the evidence of response to a prior hormonal treatment. The effect of progestin therapy in breast cancer appears to be dose dependent, with some patients demonstrating second responses following dose escalation of megestrol. Clinical use of progestins in breast cancer has been largely superseded by the advent of tamoxifen and AIs. An additional use of progestins is to stimulate appetite and restore a sense of well-being in cachectic patients with advanced stages of cancer and AIDS.

**Hormone Therapy of Prostate Cancer**

Androgens stimulate the growth of normal and cancerous prostate cells. The critical role of androgens for prostate cancer growth was established in 1941 and led to the awarding of a Nobel Prize in 1966 to Dr. Charles Huggins. These findings established androgen deprivation therapy (ADT) as the mainstay of treatment for patients with advanced prostate cancer. ADT is also given in conjunction with radiation therapy or following surgery for some men with regionally localized intermediate- to high-risk disease. In patients with metastasis, ADT is typically the standard first-line treatment either alone or in combination with chemotherapy. In patients with CRPC, ADT is used in conjunction with antiandrogens. This combination therapy is referred to as combined androgen blockade. The theoretical advantage is that the GnRH agonist will deplete testicular androgens, while the antiandrogen component competes at the receptor with residual androgens made by the adrenal glands. Combined androgen blockade provides maximal relief of androgen stimulation. Several trials suggested a benefit in 5-year survival, but toxicity and costs associated are higher than with ADT alone.

**Toxicity.** During the transient rise in LH, the resultant testosterone surge may induce acute stimulation of prostate cancer growth and a “flare” of symptoms from metastatic deposits. Patients may experience an increase in bone pain, spinal cord compression, or obstructive bladder symptoms lasting for 2–3 weeks. The flare phenomenon can be effectively counteracted with concurrent administration of 2–4 weeks of oral antiandrogen therapy, which may inhibit the action of the increased serum testosterone levels. Besides avoidance of the initial flare, GnRH antagonist therapy offers no apparent advantage compared with GnRH agonists. The early GnRH antagonists cetrorelix and abarelix (no longer marketed), although effective, are now rarely used for prostate cancer because of the risk for severe systemic allergic reactions. A newer GnRH antagonist, degarelix, is not associated with systemic allergic reactions and is approved for prostate cancer in the U.S.

**Drugs That Target the Androgen Receptor.** Antiandrogens bind to ARs and competitively inhibit the binding of testosterone and dihydrotestosterone, thereby preventing AR nuclear translocation and inhibiting transcription of downstream androgen-responsive genes. Unlike castration, antiandrogen therapy by itself does not decrease LH production; therefore, testosterone levels are normal or increased. Men treated with antiandrogen maintain some degree of potency and libido and do not have the same spectrum of side effects seen with castration. However, antiandrogen therapy is typically given in combination with ADT. Antiandrogens are classified as steroidal, including cyproterone or nonsteroidal, including enzalutamide, flutamide, bicalutamide, and nilutamide.
Enzalutamide. Enzalutamide is the most recently FDA-approved second-generation antiandrogen. It prolongs survival in patients with metastatic CRPC when given to chemotherapy naïve patients or after docetaxel therapy (Beer et al., 2014; Scher et al., 2012). Enzalutamide is a synthetic nonsteroidal antiandrogen that has 5- to 8-fold higher binding affinity for the AR compared to bicalutamide (Tran et al., 2009). Similar to other antiandrogens, enzalutamide prevents binding of androgens to the AR and reduces binding of AR to DNA and to AR coactivator proteins (see Chapter 45). Enzalutamide can also prevent translocation of AR into the cell nucleus and induces cell apoptosis.

- **ADME.** Enzalutamide has improved efficacy and potency compared to older antiandrogens. Enzalutamide is given orally once daily with a t½ of approximately 6 days. Steady-state levels are achieved in 28 days. CYF2C8 is primarily responsible for the formation of the active metabolite N-desmethyl enzalutamide.

- **Toxicity.** Similar to other antiandrogens, enzalutamide has negative effects on sexual function. Other notable side effects include gynecomastia, breast pain, fatigue, diarrhea, headache, and hot flashes. Enzalutamide crosses the blood-brain barrier, and seizures occur infrequently in approximately 1% of patients. Resistance to AR inhibitors develops frequently through mechanisms such as gene rearrangement, mutation, and acquired AR splice variants (Li et al., 2013). Studies are ongoing with newer AR-blocking agents that may overcome resistance to current antiandrogen therapies (Moilanen et al., 2015; Smith et al., 2016).

Bicalutamide. The agent bicalutamide is given once daily in conjunction with a GnRH agonist. Bicalutamide has a t½ of 5–6 days. Bicalutamide undergoes glucuronidation to inactive metabolites, and the parent compound and metabolites are eliminated in bile and urine. The t½ of bicalutamide is increased in severe hepatic insufficiency and is unchanged in renal insufficiency. Bicalutamide is well tolerated at higher doses and has reduced toxicity and improved tolerability and pharmacokinetic profiles relative to flutamide and nilutamide. Daily bicalutamide is significantly inferior compared with surgical or medical castration and should not be used as monotherapy of prostate cancer.

Nilutamide. Nilutamide is given orally once daily. It has an elimination t½ of 45 h and is metabolized to five products that are all excreted in the urine. Common side effects include mild nausea, alcohol intolerance (5%–20%), and diminished ocular adaptation to darkness (25%–40%); rarely, interstitial pneumonitis occurs.

Flutamide. Flutamide is given orally three times per day. It has a t½ of 5 h; its major metabolite, hydroxyflutamide, is biologically active. Common side effects include diarrhea, breast tenderness, and nipple tenderness. Less commonly, nausea, vomiting, and hepatotoxicity occur. Rare reports of fatal hepatotoxicity have been observed. It is used infrequently as it has the least-favorable toxicity profile of the antiandrogens.

**Drugs That Inhibit Androgen Synthesis.** In the castrate state, AR signaling, despite low steroid levels, supports continued prostate cancer growth. AR signaling may occur due to androgens produced from nongonadal sources, AR gene mutations, or AR gene amplification. Nongonadal sources of androgens include the adrenal glands and the prostate cancer cells themselves (see Figure 68–3). Androstenedione, produced by the adrenal glands, is converted to testosterone in peripheral tissues and tumors. Intratumoral de novo androgen synthesis also may provide sufficient androgen for AR-driven cell proliferation. Thus, inhibitors of androgen synthesis may be useful as secondary therapy in reducing AR signaling.

Ketoconazole. Ketoconazole is an antifungal agent that also inhibits both testicular and adrenal steroidogenesis by blocking CYP11A and primarily CYP17 (17α-hydroxylase). Ketoconazole is administered off label as secondary hormone therapy to reduce adrenal androgen synthesis in CRPC. Diarrhea and hepatic enzyme elevations limit its use as initial hormone therapy; consequent poor patient compliance reduces its efficacy. Oral ketoconazole is coadministered with hydrocortisone to compensate for inhibition of adrenal steroidogenesis. Ketoconazole has limited use in practice due to its toxicity.

Abiraterone. Abiraterone is used with prednisone for the treatment of CRPC in patients who are chemotherapy naïve or in those who have received previous docetaxel. In both settings, it prolongs survival (de Bono et al., 2011; Ryan et al., 2015).

- **Mechanism of Action.** Abiraterone is an irreversible inhibitor of 17α-hydroxylase and C-17,20-lyase (CYP17A1) activity in testicular, adrenal and prostatic cancer tissue (Figure 68–3). Abiraterone inhibition of CYP17A1 reduces the conversion of pregnenolone and progesterone to their 17α-hydroxy derivatives and reduces the synthesis of DHEA and androstenedione. Thus, circulating levels of testosterone drop to almost-undetectable levels after abiraterone administration. Abiraterone also has some activity as an AR antagonist and inhibitor of other steroid synthetic enzymes and CYP450s. Overall, abiraterone has greater potency and selectivity than ketoconazole.

- **ADME.** Abiraterone is the active metabolite of abiraterone acetate. With continuous administration, abiraterone increases ACTH levels, resulting in mineralocorticoid excess. Oral abiraterone acetate is administered with prednisone to counteract adrenal suppression. Abiraterone should be taken on an empty stomach. Abiraterone Cmax and AUC are both increased more than 10-fold when a single dose of abiraterone acetate is administered after food compared to a fasted state.

- **Toxicity.** Side effects include hepatotoxicity, joint swelling, hypokalemia, vasomotor symptoms, diarrhea, cough, hypertension, arthrythmia, urinary frequency, dyspepsia, and upper respiratory tract infection. Resistance to abiraterone, similar to enzalutamide, can occur through selection of tumor cells expressing constitutively active AR splice variants (Antonarakis et al., 2014).

**Estrogens.** High estrogen levels can reduce testosterone to castrate levels in 1–2 weeks via negative feedback on the hypothalamic-pituitary axis. Estrogen also may compete with androgens for steroid HRs and may thereby exert a cytotoxic effect on prostate cancer cells. Although estrogens reduce bone loss and are as effective as orchietomy for metastatic prostate cancer, they are no longer used clinically because of their risk for serious and potentially fatal side effects (e.g., myocardial infarctions, strokes, pulmonary emboli) as well as impotence and lethargy.

**Acknowledgment:** Paul Calabresi, Bruce Chabner, Beverly Moy, Richard J. Lee, and Matthew Smith contributed to this chapter in recent editions of this book. We have retained some of their text in the current edition.

Bibliography

This page intentionally left blank
The eye is a specialized sensory organ that is relatively secluded from systemic access by the blood-retinal, blood-aqueous, and blood-vitreous barriers. As a consequence, the eye exhibits some unusual pharmacodynamic and pharmacokinetic properties.

**Extraocular Structures**

The eye is protected by the eyelids and by the orbit, a bony cavity of the skull that has multiple fissures and foramina that conduct nerves, muscles, and vessels (Figure 69–1). In the orbit, connective (i.e., Tenon’s capsule) and adipose tissues and six extraocular muscles support and align the eyes for vision. The retrobulbar region lies immediately behind the eye (or globe). Understanding ocular and orbital anatomy is important for safe periocular drug delivery, including subconjunctival, sub-Tenon, and retrobulbar injections.

The external surface of the eyelids is covered by a thin layer of skin; the internal surface is lined with the palpebral portion of the conjunctiva, which is a vascularized mucous membrane continuous with the bulbar conjunctiva. At the reflection of the palpebral and bulbar conjunctivae is a space called the fornix. The conjunctiva and cornea. The anterior tear layer is composed primarily of lipids; the middle aqueous layer, produced by the main lacrimal gland and accessory lacrimal glands, constitutes about 98% of the tear film. Adherent to the corneal epithelium, the posterior layer is a mixture of mucus produced by goblet cells in the conjunctiva. Tears also contain nutrients, enzymes, and immunoglobulins to support and protect the cornea. The tear drainage system starts through small puncta located on the medial aspects of both the upper and lower eyelids (see Figure 69–2). With blinking, tears enter the puncta and continue to drain through the canaliculi, lacrimal sac, nasolacrimal duct, and then into the nose. The nose is lined by a highly vascular mucosal epithelium; consequently, topically applied medications that pass through this nasolacrimal system have direct access to the systemic circulation.

**Ocular Structures**

The eye is divided into anterior and posterior segments (Figure 69–3A). Anterior segment structures include the cornea, limbus, anterior and posterior chambers, trabecular meshwork, canal of Schlemm (Schlemm’s canal), iris, lens, ciliary zonule, and ciliary body. The posterior segment includes the vitreous, retina, choroid, sclera, and optic nerve.

**Anterior Segment**

**Cornea and Drug Access**

The cornea is a transparent and avascular tissue organized into five (or six) layers (Figure 69–3B). Representing an important barrier to foreign matter, including drugs, the hydrophobic epithelial layer comprises five or six cell layers. The basal epithelial cells lie on a basement membrane that is adjacent to Bowman’s layer, a distinct sheet of collagen fibers. Constituting about 90% of the corneal thickness, the stroma, a hydrophilic layer, is organized with collagen lamellae synthesized by keratocytes. Beneath the stroma lies Descemet’s membrane, the basement membrane of the corneal endothelium. A new corneal layer, Dua’s layer, has been proposed—a

distinct thin, but strong, collagen layer between the stroma and Descemet's membrane (Dua et al., 2013). Lying most posteriorly, the endothelium is a monolayer of cells adhering to each other by tight junctions. These cells maintain corneal dehydration by active transport processes and serve as a hydrophobic barrier. Hence, drug absorption across the cornea requires penetration of the trilaminar hydrophobic-hydrophilic-hydrophobic domains of the various anatomical layers.

At the periphery of the cornea and adjacent to the sclera lies a transitional zone (1- to 2-mm wide) called the limbus. Limbal structures include the conjunctival epithelium, which contains the corneal epithelial stem cells; Tenon’s capsule; episclera; corneoscleral stroma; canal of Schlemm; and trabecular meshwork (see Figure 69–3B). Limbal blood vessels, as well as the tears, provide important nutrients and immunological defense mechanisms for the cornea. The anterior chamber holds about 250 μL of aqueous humor. The peripheral anterior chamber angle is formed by the cornea and the iris root. The trabecular meshwork and canal of Schlemm are located just above the apex of this angle. The posterior chamber, with about 50 μL of aqueous humor, is defined by the boundaries of the ciliary body processes, posterior surface of the iris, and lens surface.

**Aqueous Humor Dynamics and Regulation of Intraocular Pressure**

Aqueous humor is secreted by the ciliary processes and flows from the posterior chamber, through the pupil, and into the anterior chamber and leaves the eye primarily through the trabecular meshwork and canal of Schlemm, hence to an episcleral venous plexus and into the systemic circulation. This conventional pathway accounts for 80%–95% of aqueous humor outflow and is the main target for cholinergic drugs used in glaucoma therapy. Another outflow pathway is the uveoscleral route (i.e., fluid flows through the ciliary muscles and into the suprachoroidal space), which is the target of selective prostanoids (see Glaucoma in this chapter).

The peripheral anterior chamber angle is an important anatomical structure for differentiating two forms of glaucoma: open-angle glaucoma, which is by far the most common form of glaucoma in the U.S., and angle-closure or closed-angle glaucoma. Current medical therapy of open-angle glaucoma is aimed at decreasing aqueous humor production or increasing aqueous outflow. The preferred management for angle-closure glaucoma is surgical iridectomy, by either laser or incision, but short-term medical management may be necessary to reduce the acute IOP elevation and to clear the cornea prior to surgery. Long-term IOP reduction may be necessary, especially if the peripheral iris has permanently covered the trabecular meshwork.

In anatomically susceptible eyes, anticholinergic, sympathomimetic, and antihistaminic drugs can lead to partial dilation of the pupil and a change in the vectors of force between the iris and the lens. The aqueous humor then is prevented from passing from the posterior chamber

---

*Figure 69–1*  **Anatomy of the globe in relation to the orbit and eyelids.** Routes of administration of anesthesia are represented by the blue needles.
through the pupil to the anterior chamber. The change in the lens-iris relationship leads to an increase in pressure in the posterior chamber, causing an anterior bowing of the iris, causing the iris root to be pushed against the angle wall, thereby covering the trabecular meshwork and closing the filtration angle and markedly elevating the IOP. The result is known as an acute attack of pupillary-block angle-closure glaucoma.

**Iris and Pupil**

The iris is the most anterior portion of the uveal tract, which also includes the ciliary body and choroid. The anterior surface of the iris is the stroma, a loosely organized structure containing melanocytes, blood vessels, smooth muscle, and parasympathetic and sympathetic nerves. Differences in iris color reflect individual variation in the number of melanocytes located in the stroma. Individual variation may be an important consideration for ocular drug distribution due to drug-melanin binding (see Distribution). The posterior surface of the iris is a densely pigmented bilayer of epithelial cells. Anterior to the pigmented epithelium, the dilator smooth muscle is oriented radially and is innervated by the sympathetic nervous system (Figure 69–4), which causes mydriasis (dilation). At the pupillary margin, the sphincter smooth muscle is organized in a circular band with parasympathetic innervation, which, when stimulated, causes miosis (constriction). The use of pharmacological agents to dilate normal pupils and to evaluate the pharmacological response of the pupil is summarized in Table 69–2. Agents affecting sympathetic neurotransmission in the eye are also used for the diagnostic evaluation of Horner syndrome and anisocoria.

**Ciliary Body**

The ciliary body serves two very specialized roles:

- Production and secretion of aqueous humor by the epithelial bilayer
- Accommodation by the ciliary muscle

The anterior portion of the ciliary body (pars plicata) comprises 70–80 ciliary processes with intricate folds. The posterior portion is the pars plana. The ciliary muscle is organized into outer longitudinal, middle radial, and inner circular layers. Coordinated contraction of this smooth muscle apparatus by the parasympathetic nervous system causes the zonular fibers suspending the lens to relax, allowing the lens to become more convex and to shift slightly forward. This process, known as accommodation, permits focusing on near objects and may be pharmacologically blocked by muscarinic cholinergic antagonists through a process called cycloplegia. Contraction of the ciliary muscle also puts traction on the scleral spur and hence widens the spaces within the trabecular meshwork. This last effect accounts for at least some of the IOP-lowering effect of directly acting and indirectly acting parasympathomimetic drugs. Blockade of β adrenergic receptors of the ciliary epithelium decreases production of aqueous humor.

¹Although acetylcholine and choline acetyltransferase are abundant in the corneal epithelium of most species, the function of acetylcholine in this tissue is unknown.
²The ciliary epithelium also is the target of carbonic anhydrase inhibitors. Carbonic anhydrase isoenzyme II is localized to both the pigmented and nonpigmented ciliary epithelium.
³Although β₁ adrenergic receptors mediate ciliary body smooth muscle relaxation, there is no clinically significant effect on accommodation.
Lens
The lens is suspended by the ciliary zonule, specialized fibers emanating from the ciliary body. The lens is about 10 mm in diameter and is enclosed in a capsule. The bulk of the lens is composed of fibers derived from proliferating lens epithelial cells located under the anterior portion of the lens capsule. These lens fibers are continuously produced throughout life. Aging, in addition to certain medications, such as corticosteroids, and certain diseases, such as diabetes mellitus, cause the lens to become opacified, which is termed a cataract.

Posterior Segment
Because of the anatomical and vascular barriers to both local and systemic access, drug delivery to the eye’s posterior pole is particularly challenging.

Sclera and Choroid
The outermost coat of the eye, the sclera, covers the posterior portion of the globe. The external surface of the scleral shell is covered by an episcleral vascular coat, Tenon’s capsule, and the conjunctiva. The tendons of the six extraocular muscles insert collagen fibers into the superficial scleral. Numerous blood vessels pierce the sclera through emissaria to supply and drain the choroid, ciliary body, optic nerve, and iris. Inside the scleral shell, a capillary network (vascular choroid) nourishes the outer retina. Between the outer retina and the capillary network lie Bruch’s membrane and the retinal pigment epithelium, whose tight

*Topically applied ophthalmic drugs unless otherwise noted.

*This percentage of pilocarpine is not commercially available and usually is prepared by the physician administering the test or by a pharmacist. This test also requires that no prior manipulation of the cornea (i.e., tonometry for measuring intraocular pressure or testing corneal sensation) be done so that the normal integrity of the corneal barrier is intact. Normal pupils will not respond to this weak dilution of pilocarpine; however, an Adie’s pupil manifests a denervation supersensitivity and is responsive to this dilute cholinergic agonist.
junctons provide an outer barrier between the retina and the choroid. The retinal pigment epithelium serves many functions, including vitamin A metabolism, phagocytosis of the rod outer segments, and multiple transport processes.

**Retina**

The retina is a thin, transparent, highly organized structure of neurons, glial cells, and blood vessels; it contains the photoreceptors and the rhodopsin-based G protein signaling system. The elevated IOP of glaucoma damages and causes the death of the ganglion cells (the optic nerve) that connect the retina and the brain. Glutamate, acting on NMDA receptors, can stimulate this process (Sacher et al., 1997). In theory, this offers a target for neuroprotective agents to protect against cell death, but to date no treatment other than IOP lowering has demonstrated any benefit in treating glaucoma.

**Vitreous**

Approximately 80% of the eye’s volume is the vitreous, a clear medium containing collagen type II, hyaluronic acid, proteoglycans, glucose, ascorbic acid, amino acids, and a number of inorganic salts.

**Optic Nerve**

The optic nerve is a myelinated nerve conducting the retinal output to the CNS. It comprises an intraocular portion, visible as the optic disk in the retina; an intraorbital portion; an intracanalicular portion; and an intraocular portion. The nerve is enmeshed in meninges continuous with the brain. It is susceptible to a variety of insults, ranging from traumatic damages and causes the death of the ganglion cells (the optic nerve) that connect the retina and the brain. Glutamate, acting on NMDA receptors, can stimulate this process (Sacher et al., 1997). In theory, this offers a target for neuroprotective agents to protect against cell death, but to date no treatment other than IOP lowering has demonstrated any benefit in treating glaucoma.

**Pharmacokinetics and Toxicology of Ocular Therapeutic Agents**

**Drug Delivery Strategies**

There are a number of formulations of agents and routes of drug administration that are unique to the eye (Figures 69–1 and Table 69–3). Several formulations prolong the time a drug remains on the surface of the eye. These include gels, ointments, solid inserts, soft contact lenses, and collagen shields. Prolonging the time in the cul-de-sac beneath the eyelid enhances drug absorption. Ophthalmic gels (e.g., pilocarpine 4% gel) release drugs by diffusion following erosion of soluble polymers. Ointments usually contain mineral oil and a petrolatum base and are helpful in delivering antibiotics, cycloplegic drugs, or miotic agents. Solid inserts, such as the ganciclovir intravitreal implant, provide a zero-order rate of delivery by steady-state diffusion, whereby drug is released at a more constant rate over a prolonged period of time rather than as a bolus. Drug molecules may also be encapsulated in nanoparticles for controlled release on the ocular surface.

**ADME**

The ADME pharmacokinetic principles determine the time course of drug action in the eye; however, the routes of ocular drug administration, the flow of ocular fluids, and the architecture of the eye introduce other variables specific to the eye. Most ophthalmic medications are formulated to be applied topically. Drugs also may be injected by subconjunctival, sub-Tenon’s, intracorneal, intracameral, intravitreal, and retrobulbar routes.

**Absorption.** After topical instillation of a drug, the rate and extent of absorption are determined by the dwell time of the drug in the cul-de-sac and precorneal tear film, elimination by nasolacrimal drainage, drug binding to tear proteins, drug metabolism by tear and tissue proteins, and diffusion across the cornea and conjunctiva. A drug’s residence time may be prolonged by changing its formulation or vehicle. Residence time also may be extended by blocking the egress of tears from the eye by closing the tear drainage ducts with flexible silicone (punctal) plugs. Nasolacrimal drainage contributes to systemic absorption of topically applied ophthalmic medications. Absorption from the nasal mucosa avoids first-pass metabolism by the liver; thus, topical ophthalmic medications can cause significant systemic side effects, especially when used frequently or chronically. Possible absorption pathways of an ophthalmic drug following topical application to the eye are shown schematically in Figure 69–5.

Transcorneal and transconjunctival/scleral absorption are the desired routes for localized ocular drug effects. The drug concentration gradient between the tear film and the cornea and conjunctival epithelium provides the driving force for passive diffusion across these tissues. Other factors that affect a drug’s diffusion are the size of the molecule, chemical structure, and steric configuration. Transcorneal drug penetration is a differential solubility process; the cornea resembles a trilaminar “fat-water-fat” structure corresponding to the epithelial, stromal, and endothelial layers, respectively. The epithelium and endothelium represent barriers for hydrophilic substances; the stroma is a barrier for hydrophobic compounds. Hence, an amphiphilic agent with both hydrophilic and lipophilic properties is best suited for transcorneal absorption. Drug penetration into the eye is

SECTION IX SPECIAL SYSTEMS PHARMACOLOGY
approximately linearly related to its concentration in the tear film. Certain disease states, such as corneal epithelial defects and corneal ulcers, may alter drug penetration. Medication absorption usually is increased when an anatomical barrier is compromised or removed.

**Distribution.** Topically administered drugs may undergo systemic distribution primarily by nasal mucosal absorption and possibly via local ocular distribution by transcorneal/transconjunctival absorption. Following transcorneal absorption, the aqueous humor accumulates the drug, which then is distributed to intraocular structures and potentially to the systemic circulation via the trabecular meshwork pathway (see Figure 69–3B). Melanin binding of certain drugs is an important factor in some ocular compartments. For example, the mydriatic effect of a cholinergic agonist is slower in onset in humans with darkly pigmented irides compared to those with lightly pigmented irides; drug-melanin binding is a potential reservoir for sustained drug release. Another clinically important consideration for drug-melanin binding involves the retinal pigment epithelium. In the retinal pigment epithelium, accumulation of chloroquine (see Chapter 49) causes a toxic retinal lesion known as a “bull’s-eye” maculopathy, which is associated with a decrease in visual acuity. To reduce the risk of retinal toxicity from chloroquine and related substances (e.g., hydroxychloroquine), patients receiving chronic therapy should receive periodic eye exams and lifetime cumulative doses should generally be limited to 460 g of chloroquine and 1000 g of hydroxychloroquine.

**Metabolism.** Biotransformation of ocular drugs may be significant; a variety of enzymes, including esterases, oxidoreductases, lysosomal enzymes, peptidases, glucuronide and sulfate transferases, GSH-conjugating enzymes, COMT, MAO, and 11β-hydroxysteroid dehydrogenase are found in the eye. The esterases are of particular interest, permitting development of ester prodrugs for enhanced corneal permeability (e.g., latanoprost is a prodrug for PGF2α, used for glaucoma management; loteprednol is a prednisolone analogue engineered to have limited systemic effects due to metabolic inactivation within the eye).

**Toxicity**

Most local toxic effects are due to hypersensitivity reactions or to direct toxic effects on the cornea, conjunctiva, periorcular skin, and nasal mucosa. Eye drops and contact lens solutions commonly contain antimicrobial preservatives such as benzalkonium chloride, chlorobutanol, cause a punctate keratopathy or toxic ulcerative keratopathy. All ocular medications are potentially absorbed into the systemic circulation (Figure 69–5), so systemic side effects may occur.

## Ophthalmic Uses of Drugs

### Chemotherapy of Microbial Diseases in the Eye

#### Bacterial Infections

Infectious diseases of the skin, eyelids, conjunctiva, and lacrimal excretory system are encountered regularly. Periocular skin infections are divided into preseptal and postseptal or orbital cellulitis. Depending on the clinical setting (e.g., preceding trauma, sinusitis, age of patient, relative immunocompromised state), oral or parenteral antibiotics may be administered in addition to topical medications. A number of antibiotics are formulated for topical ocular use (Table 69–4).

*Dacyroadenitis*, an infection of the lacrimal gland, is most common in children and young adults; it may be bacterial (typically *Staphylococcus aureus*, *Streptococcus spp.*) or viral (seen in mumps, infectious mononucleosis, influenza, and herpes zoster). When bacterial infection is suspected, systemic antibiotics usually are indicated.

*Dacycystitis* is an infection of the lacrimal sac. In infants and children, the disease usually is unilateral and secondary to an obstruction of the nasolacrimal duct. In adults, dacycystitis and canaliculic infections may be caused by *S. aureus*, *Streptococcus spp.*, diphtheroids, *Candida spp.*, and *Actinomyces israeli*. Any discharge from the lacrimal sac should be sent for smears and cultures. Systemic antibiotics typically are indicated.

Infectious processes of the eyelids include *hordeolum* and *blepharitis*. A hordeolum, or stye, is an infection of the meibomian, Zeis, or Moll glands in the eyelids. The typical offending bacterium is *S. aureus*, and the usual treatment consists of warm compresses and topical antibiotic (gel, drops, or ointment). *Blepharitis* is a common bilateral inflammatory process of the eyelids characterized by irritation and burning, usually associated with a *Staphylococcus* sp. Local hygiene is the mainstay of therapy: topical antibiotics frequently are used. Systemic tetracycline, doxycycline, minocycline, erythromycin, and azithromycin often are effective in reducing severe eyelid inflammation but must be used for weeks to months.

*Conjunctivitis* is an inflammatory or infectious process of the conjunctiva that varies in severity from mild hyperemia to severe purulent discharge. The more common causes of conjunctivitis include viruses, allergies, environmental irritants, contact lenses, and chemicals. Less common causes include other infectious pathogens, immune-mediated reactions, associated systemic diseases, and tumors of the conjunctiva or eyelid. Commonly reported infectious agents are adenovirus and herpes simplex virus, followed by other viral (e.g., enterovirus, coxsackievirus, measles virus, varicella zoster virus) and bacterial sources (e.g., *Neisseria spp.*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, *S. aureus*, *Moraxella lacunata*, and chlamydial spp.). *Rickettsia*, fungi, and parasites, in both cystic and trophozoite form, are rare causes of conjunctivitis. Effective management is based on selection of an appropriate antibiotic for suspected bacterial pathogens. Unless an unusual causative organism is suspected, bacterial conjunctivitis is treated empirically with a broad-spectrum topical antibiotic without obtaining a culture.

*Keratitis*, or corneal inflammation or infection, can occur at any level of the cornea. Myriad microbial agents may cause infectious keratitis, including bacteria, viruses, fungi, spirochetes, and parasites. Severe infections with tissue loss (corneal ulcers) generally are treated more aggressively than infections without tissue loss (corneal infiltrates). Mild, small, more peripheral infections usually are not cultured, and the eyes are treated with broad-spectrum topical antibiotics. In more severe, central, or larger infections, corneal scrapings for cultures and sensitivities are performed, and the patient is immediately started on intensive hourly, around-the-clock topical antibiotic therapy. A commercially available broad-spectrum antibiotic may be given, but in severe infections, specially formulated fortified antibiotics are often used. The goal of treatment is to eradicate the...
Viral Infections

Antiviral drugs used in ophthalmology are summarized in Table 69–5 (see Chapter 62 for details of these agents). The primary indications for the use of antiviral drugs in ophthalmology are viral keratitis, herpes zoster ophthalmicus, and retinitis. There are some antiviral agents which usually have a self-limited course and typically is treated by symptomatic relief of irritation, but topical ganciclovir gel may be of some benefit (Yabiku et al., 2011).

Viral keratitis, an infection of the cornea that may involve either the epithelium or stroma, is most commonly caused by herpes simplex type I and varicella zoster viruses. Less common viral etiologies include herpes simplex type II, Epstein-Barr virus, and CMV. The topical antiviral agents trifluridine and ganciclovir are both indicated for the treatment of epithelial disease due to herpes simplex infection, but trifluridine is more toxic to the corneal epithelium. Topical glucocorticoids are contraindicated in herpetic epithelial keratitis due to active viral replication. In contrast, for herpetic stromal keratitis, there is clear benefit from treatment with oral antivirals such as acyclovir in reducing the risk of recurrence (Herpetic Eye Disease Study Group, 1997, 1998; Young et al., 2010).

Herpes zoster ophthalmicus is a latent reactivation of a varicella zoster infection in the first division of the trigeminal cranial nerve. Systemic acyclovir, valacyclovir, and famciclovir are effective in reducing the severity and complications of herpes zoster ophthalmicus (Cohen and Kessler, 2016).

Viral retinitis may be caused by herpes simplex virus, CMV, adenovirus, and varicella zoster virus. With antiretroviral therapy (see Chapter 64), CMV retinitis does not appear to progress when specific anti-CMV therapy is discontinued, but some patients develop an immune recovery uveitis. Treatment usually involves long-term parenteral administration of antiviral drugs. Intravitreal ganciclovir, injected or implanted as an insert, is an effective alternative to systemic use. Acute retinal necrosis and progressive outer retinal necrosis, most often caused by varicella zoster virus, can be treated by combinations of oral, intravenous, and intravitreal administration of antiviral medications (Newman and Gooding, 2013).

**AGENT FORMULATION**
- BD: blood dyscrasia, D-RCD: drug-related corneal deposits, H: hypersensitivity
- For specific information on dosing, formulation, and trade names, refer to the Physicians’ Desk Reference for Ophthalmic Medicines, which is published annually.
- Polymyxin B is formulated for delivery to the eye in combination with bacitracin, neomycin, gramicidin, oxytetracycline, or trimethoprim. See Chapters 56–59 for further discussion of these antibacterial agents.
- Tobramycin is formulated for delivery to the eye in combination with dexamethasone or loteprednol etabonate.
Cytomegalovirus retinitis

Fungal Infections

The only currently available topical ophthalmic antifungal preparation is natamycin, a polyene. Other antifungal agents may be temporarily compounded for topical, subconjunctival, corneal intrastromal, intracameral, or intravitreal use in the United States, but their effectiveness is not well documented. Systemic antifungal agents may be necessary in the treatment of fungal keratitis.[30,31] Fungal keratitis should be considered in patients who have risk factors including immunocompromise, trauma, chronic ocular surface disease, contact lens wear, and immunosuppression (including topical steroid use). When fungal infection is suspected, samples of the affected tissues are obtained for smears, cultures, and sensitivities, and this information is used to guide drug selection.

Protozoal Infections

Parasitic infections involving the eye usually manifest themselves as a form of uveitis, an inflammatory process of either the anterior or posterior segments and, less commonly, as conjunctivitis, keratitis, and retinitis. In the United States, the most commonly encountered protozoal infections include Acanthamoeba and Toxoplasma gondii. In contact lens wearers who develop keratitis, physicians should be highly suspicious of the presence of Acanthamoeba. Risk factors for Acanthamoeba keratitis include poor contact lens hygiene, wearing contact lenses in a pool or hot tub, and ocular trauma. Treatment usually consists of a combination of topical agents. The major diamidines—propamidine isethionate in topical aqueous form and polymyxin B sulfate in ophthalmic ointment—are used successfully to treat this relatively resistant infectious keratitis. The aromatic diamidines—propamidine isethionate in topical aqueous form and polymyxin B sulfate in ophthalmic ointment—have been compounded for topical, subconjunctival, corneal intrastromal, intracameral, or intravitreal routes of administration (Table 69–6; see also Chapter 61). As with systemic fungal infections, the incidence of ophthalmic fungal infections has risen with the growing number of immunocompromised hosts. Fungal infections can involve the cornea, sclera, intraocular structures, canalicular, and orbit. Risk factors for fungal keratitis include trauma, chronic ocular surface disease, contact lens wear, and immunosuppression (including topical steroid use). When fungal infection is suspected, samples of the affected tissues are obtained for smears, cultures, and sensitivities, and this information is used to guide drug selection.

Ophthalmic Use of Autonomic Agents, Eicosanoids, and Carbonic Anhydrase Inhibitors

Autonomic drugs are used extensively for diagnostic and surgical purposes and for the treatment of glaucoma, uveitis, and strabismus. The autonomic agents used in ophthalmology and the responses (i.e., mydriasis, cycloplegia) to muscarinic cholinergic antagonists are summarized in Table 69–7. Table 69–8 presents some characteristics of eicosanoids used in ophthalmology.

Glaucoma

Glaucoma is characterized by progressive loss of retinal nerve fiber layer tissue and visual field loss. The optic nerve acquires a characteristic loss of the neuroretinal rim, frequently referred to as “cupping.” The prevalence of the disease is growing as populations age and increase around the world (Tham et al., 2014). Risk factors include increased IOP; positive family history of glaucoma; African American heritage; and possibly myopia, diabetes, and hypertension. Reducing IOP can delay glaucomatous nerve fiber or field damage. Although markedly elevated IOPs (e.g., > 30 mm Hg) usually will lead to optic nerve damage, the optic nerves in certain patients (ocular hypertensives) apparently can tolerate IOPs in the mid-to-high 20s. Other patients have progressive glaucomatous optic nerve damage despite having IOPs in the normal range; this form of the disease sometimes is called normal- or low-tension glaucoma. Regardless of the initial level, reducing the IOP delays or prevents disease progression (Collaborative Normal-Tension Study Group, 1998a, 1998b; Ederer et al., 2004; Heijl et al., 2002; Kass et al., 2002; Miglior et al., 2005). At present, the pathophysiological processes involved in glaucomatous optic nerve damage and the relationship to aqueous humor dynamics are not understood. Current

*Off-label use. Only natamycin is commercially available and labeled for ophthalmic use. All other antifungal drugs are not labeled for ophthalmic use and must be formulated for the given method of administration. For further dosing information, refer to the Physicians’ Desk Reference for Ophthalmic Medicines. For additional discussion of these antifungal agents, see Chapter 61.

Medical and pharmacotherapies are targeted at decreasing the production of aqueous humor at the ciliary body and increasing outflow through the trabecular meshwork and uveoscleral pathways. There is no consensus on the best IOP-lowering technique (Musch et al., 2011).

A stepped medical approach depends on the patient’s health, age, and ocular status, with knowledge of systemic effects and contraindications for all medications. A stepped medical approach may begin with a topical PG analogue (Table 69–8).

Due to their once-daily dosing, low incidence of systemic side effects, and potent IOP-lowering effect, PG analogues have largely replaced β adrenergic receptor antagonists as first-line medical therapy for glaucoma. The PG analogues consist of latanoprost (Figure 69–6), travoprost, bimatoprost, tafluprost, and unoprostone (discontinued in the U.S.); PGF₂α reduces IOP but has intolerable local side effects. Modifications to the chemical structure of PGF₂α have produced analogues with a more acceptable side-effect profile. PGF₂α and its analogues (prodrugs that are hydrolyzed to PGF₂α) bind to receptors for PGF₂α (FP receptors) that link to the Gₛ/PLC–IP₃–Ca²⁺/pathway. This pathway is active in isolated human ciliary muscle cells. Other cells in the eye also may express FP receptors. Theories of IOP lowering by PGF₂α range from altered ciliary muscle tension to effects on trabecular meshwork cells to release of matrix metalloproteinases and digestion of extracellular matrix materials that may impede outflow tracts.

The β receptor antagonists (Table 69–7) are currently the next most common topical medical treatment. Nonselective β blockers bind to both β₁ and β₂ receptors and include timolol, levobunolol, metipranolol, and carteolol. The β₁-selective antagonist betaxolol is available for ophthalmic use but is less efficacious than the nonselective β blockers because the β receptors of the eye are largely of the β₂ subtype. However, betaxolol is less likely to cause brunting difficulty due to blockade of pulmonary β₂ receptors. In the eye, the targeted tissues are the ciliary body epithelium and blood vessels, where β₂ receptors account for 75%–90% of the total population. How β blockade leads to decreased aqueous production and reduced IOP is uncertain. Production of aqueous humor seems to be activated by a β receptor–mediated cyclic AMP–PKA pathway; β blockade blunt adrenergic activation of this pathway. Another hypothesis is that β blockers decrease ocular blood flow, which decreases the ultrafiltration responsible for aqueous production.

When there are medical contraindications to the use of PG analogues or β receptor antagonists, other agents, such as an α-adrenergic receptor agonist (see Table 69–7) or topical CAI (Table 69–9), may be used as first-line therapy. The α₁ adrenergic agonists appear to decrease IOP by reducing aqueous humor production and by enhancing both conventional (via an α₁ receptor mechanism) and uveoscleral outflow (perhaps via PG production) from the eye. The α₁ adrenergic agonist and clonidine derivative apraclonidine is a relatively selective α₁ adrenergic agonist that is highly ionized at physiological pH, does not cross the blood–brain barrier, and is thus relatively free of the CNS effects of clonidine. Brimonidine is a selective α₂ adrenergic agonist that is lipophilic, enabling easy corneal penetration. Both apraclonidine and brimonidine reduce aqueous production and may enhance some uveoscleral outflow. Both appear to bind to presynaptic α₁ receptors. By binding to the presynaptic receptors, the drugs reduce the amount of neurotransmitter release from sympathetic nerve stimulation and thereby lower IOP. By binding to postsynaptic α₁ receptors, these drugs stimulate the Gₛ pathway, reducing cellular cyclic AMP production, thereby reducing aqueous humor production.

The development of a topical CAI was prompted by the poor side-effect profile of oral CAIs. Dorzolamide and brinzolamide both work by inhibiting CA (isoform II), which is found in the ciliary body epithelium. Inhibition of CA reduces the formation of bicarbonate ions, which reduces fluid transport and thus IOP (Table 69–9).

Any of these four drug classes can be used as additive second- or third-line therapy. In fact, the β receptor antagonist timolol has been combined with the CAI dorzolamide in a single medication and with the α₁ adrenergic agonist brimonidine. A recently released combination of brinzolamide/brimonidine is also an option. A latanoprost/timolol combination is widely available. Such combinations reduce the number of drops needed and may improve compliance.

Topical miotic agents (see Table 69–7) are less commonly used today because of their numerous side effects and inconvenient dosing. Miotics lower IOP by causing muscarinic-induced contraction of the ciliary muscle, which facilitates aqueous outflow. They do not affect aqueous production. Pilocarpine and carbachol are cholinomimetics that stimulate muscarinic receptors and are referred to as having a direct mechanism of action. Indirect agents such as echotohiophate are organophosphate inhibitors of acetylcholinesterase. Echotohiophate is relatively stable in aqueous solution and, by virtue of its quaternary ammonium structure, is positively charged and poorly absorbed. If combined topical therapy fails to achieve the target IOP or fails to halt glaucomatous optic nerve damage, then systemic therapy with a CAI is a final medication option before resorting to laser or incisional surgical treatment. The best-tolerated oral preparation is acetazolamide in sustained-release capsules (see Chapter 23), followed by methazolamide. The least well tolerated are acetazolamide tablets.

<sup>a</sup>Mydriasis and cycloplegia, or paralysis of accommodation, of the human eye occurs after one drop of atropine 1%, scopolamine 0.5%, homatropine 1%, cyclopentolate 0.5% or 1%, and tropicamide 0.5% or 1%. Recovery of mydriasis is defined by return to baseline pupil size to within 1 mm. Recovery of cycloplegia is defined by return to within 2 -diopters of baseline accommodative power. The maximal mydriatic effect of homatropine is achieved with a 5% solution, but cycloplegia may be incomplete. Maximal cycloplegia with tropicamide may be achieved with a 1% solution. Times to development of maximal mydriasis and to recovery, respectively, are as follows: for atropine, 30–40 min and 7–10 d; for scopolamine, 20–130 min and 3–7 d; for homatropine, 40–60 min and 1–3 d; for cyclopentolate, 30–60 min and 1 d; for tropicamide, 20–40 min and 6 h. Times to development of maximal cycloplegia and to recovery, respectively, are as follows: for atropine, 30–180 min and 6–12 d; for scopolamine, 30–60 min and 3–7 d; for homatropine, 30–60 min and 1–3 d; for cyclopentolate, 25–75 min and 6 h to 1 d; for tropicamide, 30 min and 6 h. Times to development of maximal mydriasis and to recovery, respectively, are as follows: for atropine, 30–180 min and 6–12 d; for scopolamine, 30–60 min and 3–7 d; for homatropine, 30–60 min and 1–3 d; for cyclopentolate, 25–75 min and 6 h to 1 d; for tropicamide, 30 min and 6 h. Times to development of maximal mydriasis and to recovery, respectively, are as follows: for atropine, 30–180 min and 6–12 d; for scopolamine, 30–60 min and 3–7 d; for homatropine, 30–60 min and 1–3 d; for cyclopentolate, 25–75 min and 6 h to 1 d; for tropicamide, 30 min and 6 h.

<sup>b</sup>Off-label use. Refer to Physicians' Desk Reference for Ophthalmic Medicines for specific indications and dosing.
and apnea in neonates and are contraindicated in children less than 2 years of age. These agents can cause CNS depression (e.g., haloperidol), and brimonidine is less likely to cause ocular allergy and therefore is more commonly used. These agents can cause CNS depression and apnea in neonates and are contraindicated in children less than 2 years of age. Systemic absorption of α2 agonists and β adrenergic antagonists can induce all the side effects of systemic administration. The use of CAIs systemically may give some patients significant problems with malaise, fatigue, depression, paresthesias, and nephrolithiasis; the topical CAIs may minimize these relatively common side effects.

**Uveitis**

Inflammation of the uvea, or uveitis, has both infectious and noninfectious causes, and medical treatment of the underlying cause (if known), in addition to the use of topical therapy, is essential. Cyclopentolate, tropicamide, or sometimes even longer-acting antimuscarinic agents such as atropine, scopolamine, and homatropine frequently are used to prevent posterior synchia formation between the lens and iris margin and to relieve ciliary muscle spasm that is responsible for much of the pain associated with anterior uveitis.

If posterior synchiae already have formed, an α adrenergic agonist may be used to break the synchia by enhancing pupillary dilation. A solution of scopolamine 0.3% in combination with 10% phenylephrine is available for this purpose. Two others, 1% hydroxyamphetamine hydrobromide combined with 0.25% tropicamide and 1% phenylephrine in combination with 0.2% cyclopentolate, are indicated only for induction of mydriasis. Topical steroids usually are adequate to decrease inflammation but sometimes must be supplemented with systemic steroids.

**Strabismus**

Strabismus, or ocular misalignment, has numerous causes and may occur at any age. Besides causing diplopia (double vision), strabismus in children may lead to amblyopia (reduced vision). Nonsurgical efforts to treat amblyopia include occlusion therapy, orthoptics, optical devices, and pharmacological agents.

An eye with hyperopia, or farsightedness, must constantly accommodate to focus on distant images. In some hyperopic children, the synkinetic accommodative-convergence response leads to excessive convergence and a manifest esotropia (turned-in eye). The brain rejects diplopia and suppresses the image from the deviated eye. If proper vision is not restored by about 6–8 years of age, the brain never learns to process visual information from that eye. The result is that the eye appears structurally normal but does not develop normal visual acuity and is therefore amblyopic. This is a fairly common cause of visual disability. In this setting, atropine (1%) instilled in the preferred seeing eye produces cycloplegia and the inability of this eye to accommodate, thus forcing the child to use the amblyopic eye (Pediatric Eye Disease Investigator Group, 2002, 2003). Echothiophate iodide also has been used in the setting of accommodative strabismus. Accommodation drives the near reflex, the triad of miosis, accommodation, and convergence. An irreversible cholinesterase inhibitor such as echothiophate causes miosis and an accommodative change in the shape of the lens; hence, the accommodative drive to initiate the near reflex is reduced, and less convergence will occur.

**Surgical and Diagnostic Uses**

For certain surgical procedures and for clinical funduscopic examination, it is desirable to maximize the view of the retina and lens. Muscarinic cholinergic antagonists and sympathomimetic agents frequently are used singly or in combination for this purpose (see Table 69–7). Intraoperatively, there are circumstances in which miosis is preferred, and two cholinergic agonists are available for intraocular use, acetylcholine and carbacol. Patients with myasthenia gravis may first present to an ophthalmologist with complaints of double vision (diplopia) or eyelid droop (ptosis); the edrophonium test is helpful in diagnosing these patients (see Chapter 10). Intraoperatively, trypan blue is marketed (as 0.06% and 0.15% ophthalmic solutions) to facilitate visualization of the anterior lens capsule during cataract surgery and for staining the retinal surface during surgical vitrectomy to guide the excision of tissue.

**Anti-inflammatory, Immunomodulatory, and Antimitotic Drugs**

**Glucocorticoids**

Glucocorticoids have an important role in managing ocular inflammatory diseases (Table 69–10 and Table 69–11). The chemistry and pharmacology of glucocorticoids are described in Chapter 46.

**Therapeutic Uses.** The glucocorticoids formulated for topical administration to the eye are dexamethasone, prednisolone, fluorometholone, loteprednol, rimexolone, and difluprednate. Because of their anti-inflammatory effects, topical corticosteroids are used in managing significant ocular allergy, external eye inflammatory diseases associated with some infections and ocular cicatricial pemphigoid, anterior uveitis, and

CHAPTER 69
OCULAR PHARMACOLOGY

postoperative inflammation following refractive, corneal, and intraocular surgery. After glaucoma filtering surgery, topical steroids can delay the wound-healing process by decreasing fibroblast infiltration, thereby reducing potential scarring of the surgical site. Steroids commonly are given systemically and by sub-Tenon’s capsule injection to manage posterior uveitis. Intravitreal injection of steroids is used to treat ARMD, diabetic retinopathy, and cystoid macular edema. An intravitreal triamcinolone formulation is approved for ocular inflammatory conditions unresponsive to topical corticosteroids and visualization during vitrectomy. Parenteral steroids followed by tapering oral doses is the preferred treatment of optic neuritis. Two ophthalmic implants, fluocinolone and dexamethasone, are marketed for the treatment of chronic, noninfectious surface disease, such as dry eye syndrome.

Ocular complications include the development of posterior subcapsular cataracts, secondary infections, and secondary open-angle glaucoma. There is a significant increase in the risk for developing secondary glaucoma when there is a positive family history of glaucoma. In the absence of a family history of open-angle glaucoma, only about 5% of normal individuals respond to topical or long-term systemic steroids with a marked increase in IOP. With a positive family history, however, moderate-to-marked steroid-induced IOP elevations may occur in up to 90% of patients. Some topical steroids (e.g., loteprednol) have been developed that reduce, but do not eliminate, the risk of elevated IOP.

Nonsteroidal Anti-Inflammatory Agents
Pharmacological properties of NSAIDS are presented in Chapter 38. Five topical NSAIDS are approved for ocular use: flurbiprofen, ketorolac, diclofenac, bromfenac, and nepafenac.

The NSAIDS are supplied as solutions and suspensions for topical ocular use to reduce ocular inflammation and cystoid macular edema. Flurbiprofen is used to counter unwanted intraoperative miosis during cataract surgery. Ketorolac is given for seasonal allergic conjunctivitis. A combination ketorolac/phenylephrine intraocular solution is available to add to intraoperative ophthalmic irrigation solutions to decrease miosis during cataract surgery. Diclofenac is used for postoperative inflammation and pain. Both ketorolac and diclofenac are effective in treating cystoid macular edema occurring after cataract surgery and in controlling pain after corneal refractive surgery. Bromfenac and nepafenac are indicated for treating postoperative pain and inflammation after cataract surgery. Topical and systemic NSAIDS occasionally have been associated with sterile corneal melts and perforations, especially in older patients with ocular surface disease, such as dry eye syndrome.

*Off-label use.
Antihistamines and Mast Cell Stabilizers

H₁ antagonists (see Chapter 32) and mast cell stabilizers are used to treat the manifestations of ocular allergies. Pheniramine (see Chapter 32) and antazoline (discontinued in the U.S.) are formulated in combination with naphazoline, a vasoconstrictor, for relief of allergic conjunctivitis; emedastine difumarate also is used. Cromolyn sodium has found some use in treating conjunctivitis that is thought to be allergen mediated, such as vernal conjunctivitis. The mast cell stabilizer lodoxamide tromethamine is available for ophthalmic use for the treatment of ocular inflammatory states such as vernal conjunctivitis, or corneal injury (corneal abrasion).

Immunosuppressants

Topical cyclosporine (Table 69–12) is approved for the treatment of chronic dry eye associated with inflammation. Use of cyclosporine is associated with decreased inflammatory markers in the lacrimal gland, increased tear production, and improved vision and comfort. Topical lifitegrast (Table 69–12) is approved to treat the signs and symptoms of dry eye disease. Lifitegrast inhibits an integrin, lymphocyte function-associated antigen 1 (LFA-1), from binding to intercellular adhesion molecule 1 (ICAM-1) which is thought to down-regulate inflammation mediated by...
**CHAPTER 69 OCULAR PHARMACOLOGY**

T lymphocytes. Interferon α-2b is used off label in the treatment of conjunctival papilloma and certain conjunctival tumors.

### Antimitotic Agents

In glaucoma surgery, the antineoplastic agents 5FU and mitomycin (Table 69–12; see details of mechanism in Chapter 66) improve the success of filtration surgery by limiting the postoperative wound-healing process.

### Therapeutic Uses

Mitomycin is used intraoperatively as a single subconjunctival application at the trabeculectomy site. 5FU may be used intraoperatively at the trabeculectomy site or subconjunctivally during the postoperative course (Fluorouracil Filtering Surgery Study Group, 1996). Both agents work by limiting the healing process; sometimes this can result in thin, ischemic, avascular tissue that is prone to breakdown. The resultant leaks can cause hypotony (low IOP) and increase the risk of infection. In corneal surgery, mitomycin has been used topically. Mitomycin can be used to reduce the risk of scarring after procedures to remove corneal opacities and prophylactically to prevent corneal scarring after photorefractive and phototherapeutic keratectomy. Mitomycin also is used to treat certain conjunctival and corneal tumors and to decrease recurrence after pterygium excision. Caution is advocated when using mitomycin in light of the potentially serious delayed ocular complications.

### Agents Used in Ophthalmic Surgery

#### Presurgical Antiseptics

Povidone iodine is formulated as a 5% sterile ophthalmic solution for use prior to surgery to prepare periorcular skin and irrigate ocular surfaces, including the cornea, conjunctiva, and palpebral fornices. Following irrigation, the exposed tissues are flushed with sterile saline. Hypersensitivity to iodine is a contraindication.

#### Viscoelastic Substances

The viscoelastic substances are agents that assist in oculary surgery by maintaining spaces, moving tissue, and protecting surfaces. These substances are prepared from hyaluronate, chondroitin sulfate, or hydroxypropylmethylcellulose and share varying degrees of the following important physical characteristics: viscosity, shear flow, elasticity, cohesiveness, and coatability. Complications associated with viscoelastic substances are related to transient elevation of IOP after surgery.

#### Ophthalmic Glue

Cyanocrylate tissue adhesive, while not FDA approved for the eye, is widely used in the management of corneal ulcerations and perforations.

Fibrin sealants are increasingly being used on the ocular surface to secure tissue such as conjunctiva, amniotic membrane, and lamellar corneal grafts.

### Anterior Segment Gases

Sulfur hexafluoride (SF6) and perfluoropropane gases are used as vitreous substitutes during retinal surgery. In the anterior segment, they are used in nonexpansile concentrations to treat Descemet's detachments, typically after cataract surgery. These detachments can cause mild-to-severe corneal edema. The gas is injected into the anterior chamber to push Descemet's membrane up against the stroma, where ideally it reattaches and clears the corneal edema. Similarly, these gases can be used after endothelial keratoplasty to help the lamellar graft adhere to the posterior cornea. SF6 is an interesting molecule: octahedral geometry about the central S; a dense (6.1 g/ml) gas; odorless and nonflammable; industrial use; and a potent greenhouse gas with a long atmospheric t1/2.

### Vitreous Substitutes

Several compounds, including gases, perfluorocarbon liquids, and silicone oils, are available as vitreous substitutes (Table 69–13). Their primary use is reattachment of the retina following vitrectomy and membrane-peeling procedures for complicated proliferative vitreoretinopathy and traction retinal detachments. The use of expansile gases carries the risk of complications from elevated IOP, subretinal gas, corneal edema, and cataract formation. The gases are absorbed over a period of days (for air) to 2 months (for perfluoropropane).

The liquid perfluorocarbons (specific gravity 1.76–1.94) are denser than vitreous and are helpful in flattening the retina when vitreous is present. Silicone oil (polydimethylsiloxanes) is used for long-term tamponade of the retina. Complications from silicone oil use include glaucoma, cataract formation, corneal edema, corneal band keratopathy, and retinal toxicity.

### Surgical Hemostasis and Thrombolytic Agents

Hemostasis has an important role in most surgical procedures and usually is achieved by temperature-mediated coagulation. Intravitreal administration of thrombin can assist in controlling intraocular hemorrhage during vitrectomy. When used intraocularly, a potentially significant inflammatory response may occur that can be minimized by thorough irrigation after hemostasis is achieved.

During intraocular surgeries to assist evacuation of a hyphema, subretinal clot, or nonclearing vitreous hemorrhage, tPA (Chapter 27) has been used off label. tPA also has been administered subconjunctivally and intracameraly (i.e., controlled intraocular administration into the anterior segment) to lyse blood clots obstructing a glaucoma filtration site. The main complication related to the use of tPA is bleeding.

**IMMUNOSUPPRESSIVE AND ANTIMITOTIC AGENTS FOR OCULAR USE**

- **Interferon α2b**: Topical solution (1 million IU/mL); subconjunctival injection (3 million IU/0.5 mL; not in the U.S.). Used for conjunctival tumors and conjunctival papilloma.
- **5-Fluorouracil**: 50-mg/mL solution. Used for glaucoma surgery, pterygium surgery, and corneal scarring and surface ablation surgery.
- **Mitomycin**: 0.2 mg/mL for topical application. Generally used as a subconjunctival application intraoperatively to prevent scarring.

---

**Presurgical Antiseptics**

- **Povidone Iodine**: 5% sterile ophthalmic solution for use prior to surgery to prepare periorcular skin and irrigate ocular surfaces, including the cornea, conjunctiva, and palpebral fornices. Typically used off-label.

---

**Viscoelastic Substances**

- **Sulfur hexafluoride (SF6)**: Octahedral geometry about the central S; dense (6.1 g/ml) gas; odorless and nonflammable; industrial use; and a potent greenhouse gas with a long atmospheric t1/2.
- **Perfluoropropane gases**: SF6 and perfluoropropane gases are used as vitreous substitutes during retinal surgery. They are used in nonexpansile concentrations to treat Descemet’s detachments, typically after cataract surgery. These detachments can cause mild-to-severe corneal edema.

---

**Vitreous Substitutes**

- **Silicone oil (polydimethylsiloxanes)**: Used for long-term tamponade of the retina. Complications include glaucoma, cataract formation, corneal edema, corneal band keratopathy, and retinal toxicity.

---

**Surgical Hemostasis and Thrombolytic Agents**

- **Tissue Plasminogen Activator (tPA)**: Used off label to lyse blood clots obstructing a glaucoma filtration site. Complications include bleeding.

**Botulinum Toxin Type A in the Treatment of Strabismus, Blepharospasm, and Related Disorders**

Two botulinum toxin type A preparations are marketed in the U.S.: onabotulinumtoxinA and abobotulinumtoxinA. OnabotulinumtoxinA is FDA approved for the treatment of strabismus and blepharospasm associated with dystonia, facial wrinkles (glabellar lines), bladder dysfunction and urinary incontinence, upper limb spasticity, axillary hyperhidrosis, spasmodic torticollis (cervical dystonia), and chronic migraine. By preventing acetylcholine release at the neuromuscular junction, botulinum toxin A usually causes a temporary paralysis of the locally injected muscles. Complications related to this toxin include double vision (diplopia), eyelid droop (ptosis), and, rarely, potentially life-threatening distant spread of toxin effect from the injection site (hours to weeks after administration).

**Agents Used to Treat Blind and Painful Eye**

Retrobulbar injection of either absolute or 95% ethanol may provide relief from chronic pain associated with a blind and painful eye. Retrobulbar chlorpromazine also has been used off label. This treatment is preceded by administration of local anesthesia. Local infiltration of the ciliary nerves provides symptomatic relief from pain, but other nerve fibers may be damaged, causing paralysis of the extraciliary muscles, including those in the eyelids, or neuroparalytic keratitis. The sensory fibers of the ciliary nerves may regenerate, and repeated injections sometimes are needed to control pain.

**Ocular Side Effects of Systemic Agents**

Certain systemic drugs have ocular side effects. These can range from mild and inconsequential to severe and vision threatening (Li et al., 2008; Pula et al., 2013). Examples are listed in the sections that follow.

**IOP and Glaucoma**

The antiseseur drug topiramate can cause choroidal effusions leading to angle-closure glaucoma.

**Retina**

Numerous drugs have toxic side effects on the retina. The antiarthritics and antimalarial medicines hydroxychloroquine and chloroquine can cause central retinal toxicity by an unknown mechanism. With normal dosages, toxicity does not appear until about 6 years after the drug is started. Stopping the drug will not reverse the damage but generally will prevent further toxicity. Tamoxifen can cause crystalline maculopathy. The antiseizure drug vigabatrin causes progressive and permanent bilateral concentric visual field constriction in a high percentage of patients.

**Optic Nerve**

The PDE inhibitors sildenafil, vardenafil, and tadalafil inhibit PDE5 in the corpus cavernosum to help achieve and maintain penile erection (Chapter 45) and to treat pulmonary arterial hypertension (Chapter 31). The drugs also mildly inhibit PDE6, which controls the levels of cyclic GMP in the retina (see Figure 69–9), causing a bluish haze or light sensitivity. Multiple medications, including ethambutol, chloramphenicol, and rifampin, can cause toxic optic neuropathy characterized by gradually progressive bilateral central scotomas and vision loss. Systemic or ocular steroids can cause elevated IOP and glaucoma. If the steroids cannot be stopped, glaucoma medications, and even filtering surgery, often are required.

**Anterior Segment**

Steroids have been implicated in cataract formation. Tamoxifen, among other drugs, has also been associated with cataracts. Rifabutin, if used in conjunction with clarithromycin or lincosamole for treatment of Mycobacterium avium complex opportunistic infections in HIV-positive persons, is associated with an iridocyclitis and even hypopyon. These conditions resolve with steroids or by stopping the medication.

**Ocular Surface**

Isotretinoin has a drying effect on mucous membranes and is associated with dry eye and severe dysfunction of the meibomian gland.

**Cornea, Conjunctiva, and Eyelids**

The cornea, conjunctiva, and eyelids can be affected by systemic medications. One of the most common drug deposits found in the cornea is from the cardiac medication amiodarone. It deposits in the inferior and central cornea in a whorl-like pattern termed cornea verticillata, appearing as fine tan or brown pigment in the epithelium. The deposits seldom affect vision and are rarely a cause to discontinue the medication. The deposits disappear slowly when the medication is stopped. Other medications, including indomethacin, atovaquone, chloroquine, and hydroxychloroquine, can cause a similar pattern. The phenothiazines, including chlorpromazine and thioridazine, can cause brown pigmentary deposits in the cornea, conjunctiva, and eyelids. They typically do not affect vision. The ocular deposits generally persist after discontinuation of the medication and can even worsen. Tetracyclines can cause a yellow discoloration of the light-exposed conjunctiva. Systemic minocycline can induce blue-gray scleral pigmentation that is most prominent in the interpalpebral zone. Certain chemotherapeutic agents, such as cytarabine, can cause temporary corneal toxicity.

**Agents Used to Assist in Ocular Diagnosis**

A number of agents are used in an ocular examination (e.g., mydriatic agents, topical anesthetics, dyes to evaluate corneal surface integrity); to facilitate intraocular surgery (e.g., mydriatic and miotic agents, topical and local anesthetics); and to help in making a diagnosis in cases of anisocoria and retinal abnormalities (e.g., intravenous contrast agents). The autonomic agents have been discussed previously. The diagnostic and therapeutic uses of topical and intravenous dyes and of topical anesthetics are discussed in the material that follows.

**Anterior Segment and External Diagnostic Uses**

Epiphora (excessive tearing) and surface problems of the cornea and conjunctiva are discussed in the material that follows.
in determining the proper fit of rigid and semirigid contact lenses. Fluorescein in combination with proparacaine or benoxinate is available for procedures in which a disclosing agent is needed in conjunction with a topical anesthetic. Fluorescein, a high-molecular-weight fluorescent solution, is used when fluorescein is contraindicated (as when soft contact lenses are in place). Rose bengal and lissamine green (available as saturated paper strips) stain devitalized tissue on the cornea and conjunctiva.

**Posterior Segment Diagnostic Uses**

The integrity of the blood-retinal and retinal pigment epithelial barriers may be examined directly by retinal angiography using intravenous administration of either fluorescein sodium or indocyanine green. These agents commonly cause nausea and may precipitate serious allergic reactions in susceptible individuals.

**Treatment of Retinal Neovascularization, Macular Degeneration, and Vitreomacular Traction**

The medical treatment of retinal neovascularization has been changing rapidly in the past several years and will likely continue to do so (Agarwal et al., 2015). Current treatment employs agents that inhibit the actions of VEGF (Table 69–14).

**Verteporfin** is approved for photodynamic therapy of the exudative form of ARM D with predominantly classic choroidal neovascular membranes. Verteporfin also is used in the treatment of predominantly classic choroidal neovascularization caused by conditions such as pathological myopia and presumed ocular histoplasmosis syndrome. Verteporfin is administered intravenously; once it reaches the choroidal circulation, the drug is light activated by a nonthermal laser source. Activation of the drug in the presence of O₂ generates free radicals, which cause vessel damage and subsequent platelet activation, thrombosis, and occlusion of choroidal neovascularization. The t₁/₂ of the drug is 5–6 h; it is eliminated predominantly in the feces. Potential side effects include headache, injection site reactions, and visual disturbances. The drug causes temporary photosensitization; patients must avoid exposure of the skin or eyes to direct sunlight or bright indoor lights for 5 days after receiving verteporfin.

**Pegaptanib**, a selective VEGF antagonist, is approved for neovascular (wet) ARMD. VEGF₁₆₅ induces angiogenesis and increases vascular permeability and inflammation, which actions likely contribute to the progression of the neovascular (wet) form of ARMD, a leading cause of blindness. Pegaptanib inhibits VEGF₁₆₅ binding to VEGF receptors. Pegaptanib (0.3 mg) is administered once every 6 weeks by intravitreal injection into the eye to be treated. Following the injection, patients should be monitored for elevation in IOP and for endophthalmitis. Rare cases of anaphylaxis/anaphylactoid reactions have been reported.

**Aflibercept** is a recombinant fusion protein, consisting of portions of human VEGF receptors 1 and 2, that acts as a soluble decoy receptor for VEGF-A. It is approved for the neovascular (wet) form of ARMD as well as macular edema following retinal vein occlusion or associated with diabetic retinopathy. Depending on the underlying disease, aflibercept (2 mg) is administered once every month by intravitreal injection into the eye for 3–5 months, followed by 2 mg once every 8 weeks. Serious side effects may include eye pain or redness, swelling, vision problems, photosensitivity, headaches, sudden numbness on one side of the body, confusion, and problems with speech and balance. The drug is contraindicated in patients who have an active eye infection or active ocular inflammation.

**Bevacizumab** is a monoclonal murine antibody that targets VEGF-A and thereby inhibits vascular proliferation and tumor growth (see Chapter 67). Intraocular use is considered off label but is routinely done. Ranibizumab is a variant of bevacizumab that has had the Fab domain affinity matured. Both drugs are delivered by intravitreal injection and often are used on a weekly or monthly basis for maintenance therapy. Both have been associated with the risk of cerebral vascular accidents. The enormous cost difference between these similar antibodies has sparked a debate about the cost-effectiveness of treatment strategies (Shaikh et al., 2015; Stein et al., 2014), especially in light of recent data indicating similar visual acuity outcomes for each medicine (CATT Research Group, 2011).

**Ocriplasmin** is a proteolytic enzyme that is used to treat vitreomacular traction. It works to dissolve the vitreous and relieve traction on the macula in the center of the retina. An interesting side effect is the possibility of lens subluxation from zonular dehiscence.

**Anesthetics in Ophthalmic Procedures**

Topical anesthetic agents used clinically in ophthalmology include proparacaine and tetracaine drops, lidocaine gel (see Chapter 22), and intranasal cocaine. Cocaine may be used intranasally in combination with topical anesthesia for cannulating the nasolacrimal system. Lidocaine and

bupivacaine are used for infiltration and retrobulbar block anesthesia for surgery. Potential complications and risks relate to allergic reactions, globe perforation, hemorrhage, and vascular and subdural injections. Both preservative-free lidocaine (1%), which is introduced into the anterior chamber, and lidocaine jelly (2%), which is placed on the ocular surface during preoperative patient preparation, are used for cataract surgery performed under topical anesthesia. Most inhalational agents and CNS depressants are associated with a reduction in IOP. An exception is ketamine, which has been associated with an elevation in IOP. In the setting of a patient with a ruptured globe, the anesthesia should be selected carefully to avoid agents that depolarize the extracellular muscles, which may result in expulsion of intraocular contents.

**Wetting Agents, Tear Substitutes, Osmotic Agents**

The current management of dry eyes usually includes instilling artificial tears and other ophthalmic lubricants. In general, tear substitutes are hypotonic or isotonic solutions composed of electrolytes, surfactants, preservatives, and some viscosity-increasing agent that prolongs the residence time in the cul-de-sac and precorneal tear film.

Common viscosity agents include cellulose polymers, polyvinyl alcohol, polyethylene glycol, polysorbate, mineral oil, glycerin, and dextran. The tear substitutes are available as preservative-containing or preservative-free preparations. The viscosity of the tear substitute depends on its exact formulation and can range from watery to gel-like. Some tear formulations also are combined with a vasoconstrictor, such as naphazoline, phenylephrine, or tetrahydrozoline. The lubricating ointments are composed of a mixture of white petrolatum, mineral oil, liquid or alcohol lanolin, and sometimes a preservative. These highly viscous formulations cause considerable blurring of vision; consequently, they are used primarily at bedtime, in critically ill patients, or in very severe dry eye conditions. A hydroxypropyl cellulose ophthalmic insert that is placed in the inferior cul-de-sac and dissolves during the day is available to treat dry eyes.

Local eye disease, such as blepharitis, ocular rosacea, ocular pemphigoid, chemical burns, or corneal dystrophies, may alter the ocular surface and change the tear composition. Appropriate treatment of the symptomatic dry eye includes treating the accompanying disease and possibly the addition of tear substitutes, punctal plugs (see Absorption), or ophthalmic cyclosporine (see Immunosuppressants). There also are a number of systemic conditions that may manifest themselves with symptomatic dry eyes, including Sjögren syndrome, rheumatoid arthritis, Stevens-Johnson syndrome, and trachoma. Treating the systemic disease may not eliminate the symptomatic dry eye complaints; chronic therapy with tear substitutes, ophthalmic cyclosporine, insertion of punctal plugs, placement of dissolvable collagen implants, or surgical occlusion of the lacrimal drainage system may be indicated. Ophthalmic cyclosporine can be used to increase tear production in patients with ocular inflammation associated with keratoconjunctivitis sicca.

The main osmotic drugs for ocular use are glycerin, mannitol, and hypertonic saline. Glycerin and mannitol are used for short-term management of acute rises in IOP. Sporadically, these agents are used intraoperatively to dehydrate the vitreous prior to anterior segment surgical procedures. Many patients with acute glaucoma do not tolerate oral medications because of nausea; therefore, intravenous administration of mannitol or acetazolamide may be preferred over oral administration of glycerin. These agents should be used with caution in patients with congestive heart failure or renal failure.

Corneal edema is a clinical sign of corneal endothelial dysfunction, and topical osmotic agents may effectively dehydrate the cornea. NaCl is available in either aqueous or ointment formulations. Topical glycerin also is available; however, because it causes pain on contact with the cornea and conjunctiva, its use is limited to urgent evaluation of filtration-angle structures. In general, when corneal edema occurs secondary to acute glaucoma, the use of an oral osmotic agent to help reduce IOP is preferred over topical glycerin, which simply clears the cornea temporarily. Reducing the IOP will help clear the cornea more permanently to allow both a view of the filtration angle by gonioscopy and a clear view of the iris as required to perform laser iridotomy.

**Vitamin A and the Visual Cycle**

Vitamin deficiencies can alter eye function, especially a deficiency of vitamin A (Table 69–15). In vision, the functional form of vitamin A is retinal; its deficiency interferes with vision in dim light, contributing to a condition known as night blindness (nyctalopia).

**Chemistry**

*Retinoid* refers to the chemical entity retinol and other closely related naturally occurring derivatives. Retinoids, which exert most of their effects by binding to specific nuclear receptors and modulating gene expression, also include structurally related synthetic analogues that need not have retinol-like (vitamin A) activity. The purified plant pigment carotene (provitamin A) is a proenkephal of vitamin A. β-Carotene is the most active

A carotenoid found in plants. The structural formulas for β-carotene and the vitamin A family of retinoids are shown in Figure 69–8. Retinoid analogues used clinically are discussed in detail in Chapter 70.

Retinal Cells and the Visual Cycle

Photoreception is accomplished by two types of specialized retinal cells, rods and cones. Rods are especially sensitive to light of low intensity; cones act as receptors of high-intensity light and are responsible for color vision. The chromophore of both rods and cones is 11-cis-retinal. The holoreceptor in rods is termed rhodopsin—a combination of the protein opsin and 11-cis-retinal attached as a prosthetic group. The three different types of cone cells (red, green, and blue) contain individual, related, photoreceptor proteins and respond optimally to light of different wavelengths. Several review articles summarized the process of photoreception (Kefalov, 2012; Saari, 2016). Figure 69–9 summarizes the signaling pathway initiated by absorption of a photon by 11-cis-retinal in rods.

Vitamin A Deficiency

Vitamin A is an essential nutrient with multiple functions in the body, including the eye (Sommer and Vyas, 2012). Humans deficient in vitamin A lose their ability for dark adaptation. Rod vision is affected more than cone vision. On depletion of retinol from liver and blood, usually at plasma concentrations of retinol of less than 0.2 mg/L (0.70 μM), the concentrations of retinol and rhodopsin in the retina fall. Unless the deficiency
is overcome, opsin, lacking the stabilizing effect of retinal, decays, and anatomical deterioration of the rod outer segment occurs.

**Vitamin A and Epithelial Structures**

In the presence of retinol or retinoic acid, basal epithelial cells are stimulated to produce mucus. Excessive concentrations of the retinoids lead to the production of a thick layer of mucus, the inhibition of keratinization, and the display of goblet cells. In the absence of vitamin A, goblet mucous cells disappear and are replaced by basal cells that have been stimulated to proliferate. These undermine and replace the original epithelium with a stratified, keratinizing epithelium. The suppression of normal secretions leads to irritation and infection. Reversal of these changes is achieved by the administration of retinol, retinoic acid, or other retinoids. When this process happens in the cornea, severe hyperkeratinization (xerophthalmia) may lead to permanent blindness (McLaren and Kraemer, 2012).

Retinoic acid influences gene expression by combining with nuclear receptors (see Figures 3–12 and 6–8). There are two families of retinoid receptors: the RARs and the RXRs. The endogenous RXR ligand is 9-cis-retinoic acid.

**Therapeutic Uses of Vitamin A**

Nutritional vitamin A deficiency causes xerophthalmia, a progressive disease characterized by nyctalopia (night blindness), xerosis (dryness), and keratomalacia (corneal thinning), which may lead to corneal perforation. Vitamin A therapy can reverse xerophthalmia; however, rapid, irreversible blindness ensues once the cornea perforates. Vitamin A also is involved in epithelial differentiation and may have a role in corneal epithelial wound healing. The current recommendation for retinopathy is to administer 15,000 IU of vitamin A palmitate daily under the supervision of an ophthalmologist and to avoid high-dose vitamin E. Clinical studies suggested a reduction in the risk of progression of some types of ARMD by high doses of vitamin C (500 mg), vitamin E (400 IU), β-carotene (15 mg), cupric oxide (2 mg), and zinc (80 mg) (Age-Related Eye Disease Study Research Group, 2001a, 2001b; Chew et al., 2014), although substituting lutein/zeaxanthin for β-carotene may be more appropriate (Age-Related Eye Disease Study Research Group, 2007; Age-Related Eye Disease Study 2 [AREDS2] Research Group, 2014).

**Bibliography**

The skin is a biologically active, multifunctional, and multicompartment organ. Medications can be applied to the skin for two purposes: to directly treat disorders of the skin and to deliver drugs to other tissues. Effective and safe use of topical pharmacological therapies requires an understanding of skin physiology and factors influencing percutaneous drug absorption and metabolism (Hwa et al., 2011; Wolff et al., 2008). General features of skin structure and percutaneous absorption pathways are outlined in Figure 70–1.

Nonpharmacological therapy is also used for treatment of skin diseases. This includes the use of parts of the electromagnetic spectrum applied by various sources, such as lasers, X-rays, visible light, and infrared light. These approaches may be used alone or to enhance the penetration or alter the nature of drugs and prodrugs. Freezing and ultrasound are other physical therapies that alter epidermal structure for direct treatment or to enhance percutaneous absorption of drugs. Chemicals are also used to decrease the effect of various wavelengths of UV light and ionizing radiation on the skin.

**Structure of Skin**
**Stratum Corneum**
The stratum corneum is the major barrier to percutaneous absorption of drugs and to the loss of water from the body. It may be considered the “nonliving” portion of the epidermis. The stratum corneum differs in thickness at different body sites, with the palm and sole the thickest followed by the general body stratum corneum, facial and postauricular area, and the eyelid and scrotum.

A drug may partition into the stratum corneum and form a reservoir that will diffuse into the rest of skin even after topical application of the drug has ceased.

**Living Epidermis**
The living layers of the epidermis (stratum basale, stratum spinosum, and stratum granulosum) with metabolically active cells comprise a layer about 100 μm thick (Figure 70–1). Intercalated in the living epidermis are pigment-producing cells (melanocytes), neuroendocrine cells (Merkel cells), dendritic APCs (Langerhans cells), and other immune cells (γ-δ T cells). In diseased epidermis, many additional immunological cells, including lymphocytes and polymorphonuclear leukocytes, may be present and be directly affected by applied drugs.

**Dermis and Its Blood Vessels**
The dermis provides mechanical strength and flexibility to the skin. It is composed primarily of fibroblasts and an extracellular matrix, including collagen, proteoglycans, glycoproteins, and, in the upper dermis, elastic fibers. Cells within the dermis that may be targets for drugs include mast cells (permanent residents and producers of many inflammatory
mediators) and infiltrating immune cells producing cytokines. The dermis also contains networks of nerves, blood vessels, and adnexal structures. The superficial capillary plexus between the epidermis and dermis is the site of the majority of the systemic absorption of cutaneous drugs (see Figure 70–1). There are large numbers of lymphatics as well. Hair follicles form a lipid-rich pathway for drug absorption but only constitute 0.1% of the total skin area, so this is not the primary route of absorption. Sweat glands are not known as a pathway for the absorption of drugs, but some drugs (e.g., griseofulvin) are excreted to the skin by this route. Below the dermis is the hypodermis or subcutaneous tissue, which provides insulation, cushioning, and an energy reservoir.

**Mechanisms of Percutaneous Absorption**

Percutaneous absorption occurs primarily through a tortuous intercellular route, with transcellular or appendageal routes playing a much smaller role. Passage through the stratum corneum is the rate-limiting step for percutaneous absorption. Preferable characteristics of topical drugs include

- low molecular mass (<500 Da);
- adequate solubility in both oil and water; and
- a high partition coefficient so the drug will selectively partition from the vehicle to the stratum corneum (Hwa et al., 2011; Tran, 2013).

Except for very small particles, water-soluble ions and polar molecules do not penetrate significantly through intact stratum corneum. The exact amount of drug entering or leaving the skin in clinical situations usually is not measured; rather, the clinical end point (e.g., reduction in inflammation) usually is the desired effect.

A hydrated stratum corneum allows more percutaneous absorption and often is achieved through the selection of drugs formulated in occlusive vehicles such as ointments and the use of plastic films, wraps, or bags for the hands and feet and shower or bathing caps for the scalp. Alternatively, medications that are impregnated on patches or tapes may be used. Occlusion may be associated with increased growth of bacteria and resultant infection (foliculitis) or maceration and breakdown of the epidermis. Absorption of most drugs across the skin is a passive process; heat generally increases penetration. Ultrasonic energy, electric currents (iontophoresis), minimally invasive microneedling, and fractional or ablative lasers also can be used to increase percutaneous absorption (Tran, 2013).

Transdermal drug delivery bypasses hepatic first-pass metabolism; however, the epidermis contains a variety of enzyme systems capable of metabolizing drugs that reach this compartment. A specific CYP isozyme, CYP26A1, metabolizes retinoic acid and may control its level in the skin (Baron et al., 2001). In addition, transporter proteins that influence influx and resultant infection (foliculitis) or maceration and breakdown of the epidermis. Absorption of most drugs across the skin is a passive process; heat generally increases penetration. Ultrasonic energy, electric currents (iontophoresis), minimally invasive microneedling, and fractional or ablative lasers also can be used to increase percutaneous absorption (Tran, 2013).

**Pharmacologic Implications of Epidermal Structure**

When proposing topical application of medications, the healthcare provider must consider multiple factors, including proper dosage and frequency of application, extent and condition of the permeability barrier, patient age and weight, physical form of the preparation to be applied, and whether intralesional or systemic administration should be used (Table 70–1). Various drug vehicles have specific advantages and disadvantages (Table 70–2). Newer vehicles, such as liposomes and microgel formulations, can enhance solubilization of certain drugs, thereby enhancing topical penetration and diminishing irritancy (Rosen et al., 2014). Children have a greater ratio of surface area to mass than adults do, so the same amount of topical drug can result in greater systemic exposure. Preterm infants have a markedly impaired barrier function until the epidermis keratinizes completely (Hwa et al., 2011). Many dermatological diseases also compromise barrier function, leading to increased percutaneous absorption.

**Glucocorticoids**

Glucocorticoids have immunosuppressive and anti-inflammatory properties. They are administered locally through topical and intralesional routes and systemically through intramuscular, intravenous, and oral routes. Mechanisms of glucocorticoid action are discussed in Chapter 46.
Cutaneous drug absorption. After application of a drug to the surface of the skin (stratum corneum), evaporation and structural/compositional alterations may occur that affect the drug's ultimate bioavailability. The stratum corneum limits drug diffusion into the lower layers and thence into the body. A number of absorptive routes are possible, singly or in combination: between the cells of the stratum corneum (intercellular), across the corneal cellular layer (transcellular), and into the concavity of a hair follicle (follicular) with its associated sebaceous glandular cells and arrector pili muscle that is innervated by the sympathetic branch of the autonomic nervous system. Melanocytes and Langerhans cells are accessible in the lower epidermis. In the epidermal and dermal layers, drugs may also reach the eccrine glands (sweat glands) and their ducts. Permeation to the dermis brings a drug in contact with lymphatics (in green) and cutaneous vessels carrying arterial and venous blood (red and blue, respectively). These vessels provide an absorptive route into the general circulation. Deeper permeation to the hypodermis may also occur.

Topical Glucocorticoids

Topical glucocorticoids have been grouped into seven classes in order of decreasing potency (Table 70–3). Potency traditionally is measured using a vasoconstrictor assay in which an agent is applied to skin under occlusion, and the area of skin blanching is assessed. Other assays of glucocorticoid potency involve suppression of erythema and edema after experimentally induced inflammation and the psoriasis bioassay, in which the effect of steroid on psoriatic lesions is quantified.

Therapeutic Uses

Many inflammatory skin diseases respond to topical or intralesional administration of glucocorticoids. Absorption varies amongst body sites and with the vehicle of the formulation. The steroid is selected on the basis of its potency, the site of involvement, and the severity of the skin disease. Often, a more potent steroid is used initially, followed by a less potent agent. Twice-daily application of topical glucocorticoids suffices; more frequent application does not improve response. Moderately potent to very potent topical corticosteroids are effective with once-daily versus twice-daily application in atopic dermatitis, and patient adherence may be improved with once-daily regimens (Williams, 2007). In general, only nonfluorinated glucocorticoids should be used on the face or in occluded areas such as the axillae or groin. Intraleisional preparations of glucocorticoids include insoluble preparations of triamcinolone acetonide and triamcinolone hexacetonide, which solubilize gradually and therefore have a prolonged duration of action.

Toxicity

Chronic use of class 1 topical glucocorticoids can cause skin atrophy, striae, telangiectasias, purpura, and acneiform eruptions. Because perioral
dermatitis and rosacea can develop after the use of fluorinated compounds on the face, they should not be used on this site. Occlusion increases the risk of HPA axis suppression.

Systemic Glucocorticoids

Systemic glucocorticoid therapy is used for severe dermatological illnesses and generally is reserved for allergic contact dermatitis to plants (e.g., poison ivy) and for life-threatening vesiculobullous dermatoses such as pemphigus vulgaris and bullous pemphigoid. Chronic administration of oral glucocorticoids is problematic, given the side effects associated with their long-term use (see Chapter 46).

Daily morning dosing with prednisone generally is preferred, although divided doses occasionally are used to enhance efficacy. Fewer side effects are seen with alternate-day dosing; if chronic therapy is required, prednisone usually is tapered to every other day as soon as practical. Pulse therapy using large intravenous doses of methylprednisolone sodium succinate is an option for severe resistant pyoderma gangrenosum, pemphigus vulgaris, systemic lupus erythematosus with multisystem disease, and dermatomyositis. The dose of intravenous methylprednisolone usually is 0.5–1 g given over 2–3 h. More rapid infusion has been associated with increased rates of hypotension, electrolyte shifts, and cardiac arrhythmias.

**Toxicity and Monitoring**

Oral glucocorticoids have numerous systemic effects, as discussed in Chapter 46. Most side effects are dose dependent.

### Retinoids

Retinoids comprise natural and synthetic compounds that exhibit vitamin A–like biological activity or bind to nuclear receptors for retinoids. Characteristics of topical and systemic retinoids are summarized in Tables 70–4 and 70–5, respectively.

and alitretinoin (9-cis retinoic acid; vitamin A acid), isotretinoin (13-cis retinoic acid), and alitretinoin (9-cis retinoic acid). *Second-generation retinoids*, also known as aromatic retinoids, include acitretin. *Third-generation retinoids* were designed to optimize receptor-selective binding and include tazarotene, bexarotene, and adapalene.

- **Mechanism of Action.** Retinoids exert their effects on gene expression by activating two families of receptors, RARs and RXRs, which are members of the steroid receptor superfamily. Both retinoid receptor families have three isoforms (α, β, and γ), which are expressed in unique combinations in individual tissues and cells. On binding to a retinoid, RARs and RXRs form heterodimers (RAR-RXR) that subsequently bind specific DNA sequences called RAREs that activate transcription of genes whose products produce both the desirable pharmacological effects and the unwanted side effects of these drugs (see Tables 6–5, 70–4 and 70–5, and Figure 6–13).

- **Targeted Therapeutic Actions.** Retinoids that target RARs predominantly affect cellular differentiation and proliferation, whereas retinoids that target RXRs predominantly induce apoptosis. Hence, tretinoin, adapalene, and tazarotene, which target RARs, are used in acne, psoriasis, and photodamage (disorders of differentiation and proliferation), whereas bexarotene and alitretinoin, which target RXRs, are used in CTCL and Kaposis sarcoma, respectively, to induce apoptosis of malignant cells.

- **Retinoid Toxicity.** Acute retinoid toxicity is similar to vitamin A intoxication. Side effects of systemic retinoids include dry skin, nosebleeds from dry mucous membranes, conjunctivitis, reduced night vision, hair loss, alterations in serum lipids and transaminases, hypothyroidism, inflammatory bowel disease flare, musculoskeletal pain, pseudotumor cerebri, and mood alterations. RAR-selective retinoids are more associated with mucocutaneous and musculoskeletal symptoms, whereas RXR-selective retinoids induce more psychophysical changes. Because all oral retinoids are potent teratogens, they should be used carefully in females of childbearing potential and not in pregnant patients.

| Topical Retinoids | Through incompletely understood mechanisms, topical retinoids correct abnormal follicular keratinization, reduce Propionibacterium acnei counts, and reduce inflammation, thereby making them the cornerstone of acne therapy. Topical retinoids are first-line agents for noninflammatory (comedonal) acne and often are combined with other agents in the management of inflammatory acne.

Fine wrinkles and dyspigmentation, two important features of photodamage, are also improved with topical retinoids. Within the dermis, this is believed to result from inhibition of AP-1, which normally activates synthesis of matrix metalloproteinases in response to UV irradiation (Thielitz and Golnik, 2008). In the epidermis, retinoids induce epidermal hyperplasia in atrophic skin and reduce keratinocyte atypia.

**Toxicity and Monitoring**

Adverse effects of all topical retinoids include erythema, desquamation, burning, and stinging (see relative irritancy in Table 70–4). These effects often decrease with time and are lessened by concomitant use of emollients. Patients may also experience photosensitivity reactions (enhanced reactivity to UV radiation) and have a significant risk for severe sunburn. Although there is little systemic absorption of topical retinoids and no alteration in plasma vitamin A levels with their use, topical retinoids are not recommended for use during pregnancy.

**Available Agents; Clinical Use**

**Tretinoin** (all-trans-retinoic acid) is photolabile and should be applied once nightly for acne and photodamage. Benzoyl peroxide also inactivates tretinoin and should not be applied simultaneously. Formulations with copolymer microspheres or prepolyol prepolymer 2 that gradually release tretinoin to decrease irritancy are available and are less susceptible to oxidation by benzoyl peroxide and photodegradation. **Adapalene** has similar efficacy to tretinoin, but unlike tretinoin, it is stable in sunlight or the presence of benzoyl peroxide and tends to be less irritating.

**Tazarotene** is approved for the treatment of psoriasis, photodamage, facial wrinkles, and acne vulgaris. Tazarotene gel, applied once daily, may be used as monotherapy or in combination with other medications, such as topical corticosteroids, for the treatment of localized plaque psoriasis. Topical corticosteroids improve the efficacy of therapy and reduce the side effects of burning, itching, and skin irritation that are commonly associated with tazarotene.

**Alitretinoin** is a retinoid that binds all types of retinoid receptors, both RARs and RXRs. It is approved for treatment of cutaneous lesions.
of Kaposi sarcoma, with its application titrated up from twice daily to three or four times daily as tolerated. Alitretinoin should not be applied concurrently with insect repellants containing diethyltoluamide (DEET) because it may increase DEET absorption.

**Bexarotene** is approved for early-stage (IA and IB) CTCL. Its application is titrated up from every other day to two to four times daily over several weeks to improve patient tolerance. Concurrent application of bexarotene with insect repellants containing DEET is not recommended because it may increase DEET absorption.

### Systemic Retinoids

Systemic retinoids (Table 70–5) are approved for the treatment of acne, psoriasis, and CTCL (Desai et al., 2007).

#### Therapeutic Uses and Contraindications

Off-label uses include ichthyosis, Darier disease, pityriasis rubra pilaris, rosacea, hidradenitis suppurativa, chemoprevention of malignancy, lichen sclerosus, subacute lupus erythematosus, and discoid lupus erythematosus. Absolute contraindications include use by women who are pregnant, planning to become pregnant, or breastfeeding. Relative contraindications include leukopenia, alcoholism, hyperlipidemia, hypercholesterolemia, hypothyroidism, and significant hepatic or renal disease.

#### Toxicity and Monitoring

Acute toxicities may include mucocutaneous or laboratory abnormalities; bony changes may occur after chronic use at high doses. Mucocutaneous side effects may include cheilitis, xerosis, blepharoconjunctivitis, cutaneous photosensitivity, photophobia, myalgia, arthralgia, headaches, alopecia, nail fragility, and increased susceptibility to staphylococcal infections. Some patients develop a “retinoid dermatitis” characterized by erythema, pruritus, and scaling. Very rarely, patients may develop pseudotumor cerebri, especially when systemic retinoids are combined with tetracyclines.

There are reports that chronic administration at higher doses can cause diffuse idiopathic skeletal hyperostosis (DISH) syndrome, premature epiphyseal closure, and other skeletal abnormalities (Desai et al., 2007). Systemic retinoids are highly teratogenic. There is no safe dose during pregnancy. Prescribing of isotretinoin in the U.S. is restricted via the risk-mitigation iPLEDGE system.

Serum lipid elevation is the most common laboratory abnormality. Less common laboratory abnormalities include elevated transaminases, decreased thyroid hormone, and leukopenia. A baseline evaluation of serum lipids, serum transaminases, and CBC should be obtained prior to starting any systemic retinoids. These laboratory values are usually subsequently checked monthly for the first 3–6 months and once every 3 months thereafter. In addition, two negative pregnancy tests on separate occasions are required for females of childbearing potential prior to starting acitretin or isotretinoin; bexarotene requires one negative pregnancy test within the week prior to initiating therapy. Monthly pregnancy tests should be obtained for females of childbearing potential.

#### Available Agents and Clinical Use

**Isotretinoin** is approved for the treatment of recalcitrant and nodular acne vulgaris. The drug has remarkable efficacy in severe acne and may induce prolonged remissions after a single course of therapy. Clinical effects generally are noted within 1–3 months of starting therapy. Approximately one-third of patients will relapse, usually within 3 years of stopping therapy. Although most relapses are mild and respond to conventional management with topical and systemic antiacne agents, some may require a second course of isotretinoin. Systemic absorption is improved when taken with a high-fat meal. An isotretinoin-Lidose formulation (a eutectic mixture of drug and lipids in a hard gelatin capsule) may be given without respect to meals.

**Acitretin** is approved for use in the cutaneous manifestations of psoriasis. Clinical effect may begin within 4–6 weeks, with the full clinical benefit occurring at 3–6 months. Acitretin has a t₁/₂ of about 50 h; however, when combined with alcohol, acitretin is esterified in vivo to produce etretinate, which has a t₁/₂ of more than 3 months. It is not known how much alcohol (i.e., cough syrup or other alcohol-based medications) is required to induce this conversion. Thus, female patients of childbearing potential should avoid pregnancy for 3 years after receiving acitretin to avoid retinoid-induced embryopathy.

Bexarotene is a retinoid that selectively binds RXRs. Oral and topical formulations of bexarotene are approved for use in patients with CTCL. Bexarotene reportedly induces apoptosis of malignant cells (Jawed et al., 2014). Because CYP3A4 metabolizes bexarotene, inhibitors of CYP3A4 (e.g., imidazole antifungals, macrolide antibiotics) will increase and inducers of CYP3A4 (e.g., rifamycins, carbamazepine, dexamethasone, efavirenz, phenobarbital) will decrease plasma levels of bexarotene. Side effects are more common than with other retinoids, with an increased incidence of significant lipid abnormalities and hypothyroidism secondary to a reversible RXR-mediated suppression of TSH gene expression, pancreatitis, leukopenia, and GI symptoms. Thyroid function should be measured before initiating therapy and periodically thereafter.

**Vitamin Analogues**

**Calcipotriene**
Calcipotriene is a topical vitamin D analogue that is used in the treatment of psoriasis.

**Mechanism of Action**
Calcipotriene exerts its effects through the VDR (see Chapter 48). On binding the VDR, the drug-receptor complex associates with the RXR-α and binds to vitamin D response elements on DNA, increasing expression of genes that modulate epidermal differentiation and inflammation, leading to improvement in psoriatic plaques (Menter et al., 2009a).

**Therapeutic Use**
Calcipotriene is applied twice daily to plaque psoriasis on the body, often in combination with topical corticosteroids. Hypercalcemia and hypercalciuria may develop when the cumulative weekly dose exceeds the recommended 100 g/week limit and resolves within days of discontinuation of calcipotriene (Menter et al., 2009a). Calcipotriene also causes perilesional irritation and mild photosensitivity. Concomitant administration of topical corticosteroids will reduce the irritation. Calcipotriene has been used off label for multiple conditions, including morphea, vitiligo, and congenital ichthyoses.

**β-Carotene**
β-Carotene is a precursor of vitamin A that is in green and yellow vegetables. No β-carotene products are currently FDA approved. Dietary supplementation with β-carotene is used in dermatology to reduce skin photosensitivity in patients with erythropoietic protoporphyria. The mechanism of action is not established but may involve an antioxidant effect that decreases the production of free radicals or singlet oxygen. A meta-analysis concluded that β-carotene, vitamin A, and vitamin E, given singly or combined with other antioxidant supplements, did not provide any benefit in lowering mortality or decreasing the risk of cerebrovascular accident. In addition, use of β-carotene and vitamin E led to an increase in all-cause mortality (Bjelakovic et al., 2012). The FDA’s maximum recommended therapeutic dose (MRTD) for β-carotene is 0.05 mg/kg/d.

**Photochemotherapy**
Phototherapy and photochemotherapy are treatment methods in which UV or visible radiation is used to induce a therapeutic response either alone (phototherapy) or in the presence of an exogenous photosensitizing drug (photochemotherapy) (Table 70–6). Patients treated with these modalities should be monitored for concomitant use of other potential photosensitizing medications, such as phenothiazines, thiazides, sulfonamides, NSAIDs, sulfonylureas, tetracyclines, and benzodiazepines.

---

CNS, central nervous system; CTCL, cutaneous T cell lymphoma; GI, gastrointestinal; HSV, herpes simplex virus; UVA, ultraviolet A.
The UV radiation region may be subdivided into UVA1 (340–400 nm), UVA2 (320–340 nm), UVB (290–320 nm), and UVC (100–290 nm). UVC radiation is almost completely absorbed by the ozone layer and atmosphere so that measurable amounts do not reach Earth’s surface. UVA and UVB exposure can cause sunburns, photoaging, and skin cancer development. UVB is the most erythrogenic and melanogenic, and it is the major action spectrum for sunburn, tanning, skin cancer, photoaging, and cutaneous vitamin D synthesis. UVA is only a thousandth as erythrogenic as UVB but penetrates more deeply into the skin and contributes substantially to photoaging and photosensitivity diseases. UVA is also able to penetrate clouds and glass, so exposure may occur even in the shade or while indoors. Both UVA and UVB cause photoinnate suppression, an effect that is utilized for therapy of certain dermatological conditions.

PUVA: Psoralens and UVA

The PUVA combines UVA light with photosensitizing compounds called psoralens. Orally administered methoxsalen (8-methoxypsoralen) followed by UVA (PUVA) is FDA approved for the treatment of vitiligo and psoriasis. It is also used off label in several other inflammatory or lymphoproliferative cutaneous disorders (Tortonch and Chiu, 2014).

Chemistry and Mechanism of Action

Psoralens are lipophilic, naturally occurring furocumarins found in some plants. Synthetic versions are also available. The action spectrum for PUVA is between 320 and 340 nm. Psoralens intercalate into the DNA strand, and two distinct photo reactions take place on UVA exposure. Type I reactions involve the oxygen-independent photoaddition of psoralens to pyrimidine bases in DNA. Type II reactions are oxygen dependent and involve the transfer of energy to molecular oxygen, creating reactive oxygen species. Through incompletely understood mechanisms, these phototoxic reactions stimulate melanocytes and induce antiproliferative, immunosuppressive, and anti-inflammatory effects.

Pharmacokinetics

Formulations of solubilized methoxsalen in a gel matrix are rapidly absorbed tid after oral administration, whereas older microcrystalline forms are absorbed slowly and incompletely. Fatty foods slow absorption and decrease peak blood levels. There is significant, but saturable, first-pass elimination in the liver. Peak photosensitivity varies significantly between individuals but typically is maximal 1–2 h after ingestion. Methoxsalen has a serum t1/2 of about 1 h, but the skin remains sensitive to light for 8–12 h.

Therapeutic Uses

Oral methoxsalen is available as a single 10-mg strength either as soft gelatin capsules (solubilized) or hard gelatin capsules (micronized crystals). The dose is 10–70 mg, depending on weight (0.4–0.6 mg/kg), taken about 1.5–2 h before UVA exposure. Though administration with food can decrease absorption, it may minimize nausea. Topical application of psoralens followed by UVA exposure (topical PUVA) is also used for treatment. A lotion containing 1% methoxsalen is available for topical application for vitiligo. The methoxsalen lotion or capsules can be diluted in bathwater and used topically for localized palmoplantar (soak PUVA) or more diffuse (bath PUVA) areas to minimize systemic absorption. An extracorporeal solution is available for CTCL (see Photopheresis).

Approximately 70%–100% of psoriatic patients have clearing or virtual clearing of skin disease within about 24 treatments with PUVA. Remission typically lasts 3–6 months; thus, patients often require maintenance therapy with intermittent PUVA or other agents. Vitiligo typically requires between 150 and 300 treatments. Localized vitiligo can be treated with topical PUVA and more extensive disease with systemic administration. PUVA also is employed off label in the treatment of atopic dermatitis, alopecia areata, lichen planus, and urticaria pigmentosa.

Toxicity and Monitoring

The major side effects of PUVA are listed in Table 70–6. Phototoxicity is characterized by erythema, edema, blistering, and pruritus. Ocular toxicity can be prevented by wearing UVA-blocking glasses on the day of treatment. The risk of nonmelanoma skin cancer is dose dependent, with the greatest risk in those receiving more than 200–250 treatments (Tortonch and Chiu, 2014). There is a possible association between extensive PUVA exposure and melanoma, but there has been conflicting evidence regarding this association.

Photopheresis

Extracorporeal photopheresis (ECP) is a process in which extracorporeal peripheral blood mononuclear cells are separated using a leukapheresis-based method then exposed to UVA radiation in the presence of methoxsalen (Perotti and Sniecinski, 2013). Methoxsalen is injected directly into the extracorporeal plasma before radiation and refinement. The treated lymphocytes are returned to the patient, undergoing apoptosis over 48–72 h. The ECP is used for CTCL and off label for various other T-cell–mediated diseases, including graft-versus-host disease, transplantation rejection, and sclerodermatitis. Patients receive ECP therapy on two consecutive days every 2–4 weeks, and intervals are increased as the patient improves (Jawed et al., 2014). ECP can be combined with adjutant therapies, including PUVA, topical chemotherapy, systemic chemotherapy, radiation, biological agents, and retinoids.

Photodynamic Therapy

Photodynamic therapy combines the use of photosensitizing drugs and visible light for the treatment of dermatological disorders. Two drugs are approved for topical PDT: aminolevulinic acid and methylaminolevulinate. However, methylaminolevulinate is currently not commercially available in the U.S. Both are prodrugs that are converted into protoporphyrin IX within living cells (Figure 70–2). In the presence of specific wavelengths of light (see Table 70–6) and O₂, protoporphyrin produces reactive oxygen species that oxidize cell membranes, proteins,
and mitochondrial structures, leading to apoptosis. The epidermis, seba-
ceous glands, and neoplastic cells accumulate more porphyrin than other
cutaneous cells and structures, providing some preferential targeting of
therapy (Rkein and Ozog, 2014). PDT is approved for use on precancero-
ous actinic keratosis. It is also used off label for superficial nonmelanoma
skin cancers, acne, and photorejuvenation. Incoherent (nonlaser) and
laser light sources have been used for PDT. The wavelengths chosen must
include those within the action spectrum of protoporphyrin (see Table 70–6)
and ideally those that permit maximum skin penetration. Light sources in
use emit energy predominantly in the blue portion (maximum porphyrin
absorption) or the red portion (better tissue penetration) of the visible
spectrum. Because the $t_{1/2}$ of the accumulated porphyrins is about 30 h,
patients should protect their skin from sunlight and intense light for at
least 48 h after treatment to prevent photototoxic reactions.

**Sunscreens**

Sunscreens provide temporary photoprotection from the acute and
chronic effects of sun exposure. They are an important component of
a comprehensive sun protection approach along with minimizing sun
exposure and using photoprotective gear. The regular use of sunscreen is
efficacious in reducing photocarcinogenesis and photoaging (Mancebo
et al., 2014). The SPF is defined as the ratio of the minimal dose of incident
sunlight that will produce erythema (sunburn) on skin with the sunscreen in
place to the dose that evokes the same reaction on skin without the
sunscreen. SPF is primarily a measure of UVB protection and does not
provide information regarding UVA coverage. In 2011, the FDA pub-
lished new guidelines for labeling and effectiveness testing of sunscreens
(Mancebo et al., 2014). UVA protection is now assessed using the CW
method, and products with a CW of 370 nm or greater may be labeled as “broad spectrum.” Sunscreens providing broad-spectrum coverage
with an SPF 15 or greater may include a claim on their labeling that use “decreases risk of skin cancer and early aging caused by the sun.” Sun-
screens should be applied liberally 15–30 min prior to sun exposure and
reapplied every 2 h. If activities involve swimming or sweating, water-
resistant sunscreens are recommended and should be reapplied every 40
or 80 min depending on their labeling.

The major active ingredients of available sunscreens include organic
gagents (“chemical blockers”) that absorb UV radiation in the UVB or UVA
ranges, then convert it to heat energy and inorganic agents (“physical block-
ers”) that contain particulate materials that act by scattering or reflecting
visible, UV, and infrared radiation to reduce its transmission to the skin.
The current FDA-approved active sunscreen ingredients are listed next.

**Inorganic Agents**

The two inorganic agents available in the U.S. are zinc oxide and titanium
dioxide. They provide UVA and UVB protection. Newer micronize and nan-
osize particle formulations are less opaque and more cosmetically appealing.

**Organic UVA Filters**

Currently available UVA filters in the U.S. include benzophenones (oxy-
benzzone, diarylbenzene, sulisobenzone); dibenzoylmethanes (avobenzone);
anthralates (meradimate); and camphors (ecamsule). Additional UVA filters
are used in other countries but are not currently available in the U.S.

**Organic UVB Filters**

There are numerous UVB filters, including aminobenzoates (PABA and
padimate O); cinnamates (cinoxate, octinoxate); salicylates (trolamine
salicylate, homosalate, octisalate); octocrylene; and ensulizole.

**Antihistamines**

Histamine (see Chapter 39) is a potent vasodilator, bronchial smooth
muscle constrictor, and stimulant of nociceptive itch receptors. Addi-
tional chemical itch mediators acting as pruritogens on C fibers include
neuropeptides, prostaglandins, serotonin, acetycholine, and bradykinin.

Furthermore, receptor systems (e.g., vanillloid, opioid, and cannabinoid
receptors) on cutaneous sensory nerve fibers may modulate itch and offer
novel future targets for antipruritic therapy.

Histamine is in mast cells, basophils, and platelets. Human skin mast
cells express $H_1$, $H_2$, and $H_3$ receptors but not $H_4$ receptors. Both $H_1$
and $H_2$ receptors are involved in wheal formation and erythema, whereas
only the $H_3$ receptor agonists cause pruritus (see Chapter 39). However,
blockade of $H_3$ receptors does not totally relieve itching, and combina-
tion therapy with $H_1$ and $H_3$ antagonists may be superior to the use of $H_4$
agonists alone.

Oral antihistamines, particularly $H_1$ receptor antagonists, have anticho-
linergetic activity and are sedating (see Chapter 39), making them useful for
the control of pruritus. First-generation sedating $H_1$ receptor antagonists
include hydroxyzine, diphenhydramine, promethazine, and cyproheptadine
(Simons and Simons, 2008). Doxepin is a good alternative to traditional
oral antihistamines for severe pruritus. A 5% topical cream formulation of
doxepin, which can be used in conjunction with low- to moderate-
potency topical glucocorticoids, is also available. The antipruritic effect
from topical doxepin is comparable to that of low-dose oral doxepin ther-
apy. Allergic contact dermatitis to doxepin has been reported. Topical
diphenhydramine formulations available OTC also carry a significant risk
of allergic contact dermatitis. Second-generation $H_3$ receptor antagonists
lack anticholinergic side effects and are described as nonsedating largely
because they do not cross the blood-brain barrier (Simons and Simons,
2008). They include cetirizine, levocetirizine, loratadine, desloratadine,
and fexofenadine.

**Antimicrobial Agents**

**Antibiotics**

Antibiotic agents are frequently used to treat SSTIs. Several antimicro-
bial agents, such as tetracyclines, macrolides, and dapsone, also have
anti-inflammatory properties, which make them useful for noninfectious
conditions, such as acne vulgaris, rosacea, granulomatous diseases, neu-
 trophic dermatoses, and autoimmune bullous diseases (Bhatia, 2009).

Topical agents are very effective for the treatment of superficial bac-
terial infections and acne vulgaris (Drucker, 2012). Systemic antibiotics
also are prescribed commonly for acne and deeper bacterial infections.
The pharmacology of individual antibacterial agents is discussed in
Section VI, Chemotherapy of Microbial Diseases. Only the topical and
systemic antibacterial agents principally used in dermatology are dis-
cussed here.

**Acne**

Acne vulgaris is the most common dermatological disorder treated
with either topical or systemic antibiotics (Eichenfield et al., 2013). The
gram-positive anaerobe Propionibacterium acnes is a component of nor-
mal skin flora that proliferates in the obstructed, lipid-rich lumen of the
pilosebaceous unit, where $O_2$ tension is low. Propionibacterium acnes
generates free fatty acids from sebum and interacts with toll-like receptors,
which promotes microcomedo formation and inflammatory lesions (Das
and Reynolds, 2014). Suppression of cutaneous $P$. acnes with antibiotic
therapy is correlated with clinical improvement.

**Topical antimicrobials** commonly used in acne include benzoyl per-
oxide, clindamycin, erythromycin, and antibiotic–benzoyl peroxide com-
binations. Topical monotherapy with clindamycin or erythromycin is not
recommended due to a slower onset of action and potential for develop-
ment of bacterial resistance; therefore, addition of benzoyl peroxide or use
of combination antibiotic–benzoyl peroxide products is recommended to
improve efficacy and decrease emergence of antibiotic-resistant bacteria
(Eichenfield et al., 2013). Other topical antimicrobials used in treating
acne include azelaic acid, dapsone, metronidazole, sulfaacetamide, and
sulfacetamide/sulfur combinations.

**Systemic therapy** is prescribed for patients with acne vulgaris that is
more extensive or resistant to topical therapy. There are data to support the
use of tetracyclines (doxycycline, minocycline, tetracycline); macrodilides (azithromycin, erythromycin); and trimethoprim-sulfamethoxazole. Other antibiotics that decrease the extent of the infection or the inflammatory response to *P. acnes* may be effective as well. Antibiotics usually are administered once or twice daily, and 6–8 weeks is required for visible clinical results, with maximum effect sometmes requiring 3–6 months (Eichenfield et al., 2013). Doses are tapered after control is achieved. Concomitant use with topical benzoyl peroxide may decrease development of antibiotic-resistant bacteria.

The tetracyclines are the most commonly employed antibiotics because they are inexpensive, effective, and safe. They should not be used during pregnancy or in patients younger than 8 years. Although agents in the tetracycline class are antimicrobials, efficacy in acne may be more dependent on anti-inflammatory activity. Minocycline and doxycycline have better GI absorption than tetracycline and may be given with food to minimize GI side effects. Minocycline may be less photosensitizing than either tetracycline or doxycycline. Minocycline's adverse effects may include vestibular toxicity, hyperpigmentation of the skin and mucosa, serum sickness–like reactions, and drug-induced lupus erythematosus. With all the tetracyclines, vaginal candidiasis is a common complication that is readily treated with administration of antifungal drugs.

**Cutaneous Bacterial Infections**

Numerous organisms may cause cutaneous infections ranging from benign to life-threatening. Clinical presentation and treatment depend on the depth of cutaneous involvement, immune status of the patient, causative organism, and local antibiotic resistance patterns (Rajan, 2012; Stevens et al., 2014). Gram-positive organisms, including *Staphylococcus aureus* and *Streptococcus pyogenes*, are the most common cause of SSTIs. Patients who are diabetic or immunosuppressed are at risk for severe, recurrent, or atypical infections.

**Topical Therapy.** Topical therapy is frequently used for superficial bacterial infections, wounds, and burns. The use of topical antibiotics on clean surgical wounds without signs of infection is not recommended as it does not reduce the rate of infection compared to nonantibiotic ointment or no ointment, and there is a risk of contact dermatitis to topical antibiotics (Levender et al., 2012) and counterproductive selection of resistant bacterial strains.

*Mupirocin.* Mupirocin inhibits protein synthesis by binding to bacterial isoleucyl-tRNA synthetase. Mupirocin is effective for treatment of *S. aureus* and *S. pyogenes*, but it is inactive against normal skin flora or anaerobes. Mupirocin is available as a 2% ointment or cream, applied twice or three times daily for 5–10 days. The recommended regimen for impetigo is twice daily for 5 days (Stevens et al., 2014). A nasal formulation is indicated to eradicate MRSA nasal colonization. It is applied intranasally twice a day for 5 days and often combined with daily chlorhexidine or dilute sodium hypochlorite washes for the body. Prolonged suppression may be achieved with repeat monthly courses.

*Retapamulin.* Retapamulin selectively inhibits bacterial protein synthesis by interacting at a unique site on the 50S subunit of bacterial ribosomes. It is active against multiple gram-positive organisms, including *S. aureus* and *S. pyogenes*, and against anaerobes. Retapamulin ointment 1% is FDA approved for the topical treatment of impetigo caused by susceptible strains of *S. aureus* or *S. pyogenes* in patients 9 months or older. The recommended regimen for impetigo is twice daily for 5 days (Stevens et al., 2014).

*Bacitracin, Neomycin, and Polymyxin B.* These agents are sold alone or in various combinations with other ingredients (e.g., hydrocortisone, lidocaine, or pramoxine) in a number of OTC formulations. Bacitracin inhibits staphylococci, streptococci, and gram-positive bacilli. Neomycin is active against staphylococci and most gram-negative bacilli. Polymyxin B is active against aerobic gram-negative bacilli, including *Pseudomonas aeruginosa*. Both bacitracin and neomycin are relatively common causes of allergic contact dermatitis, especially in patients with stasis dermatitis or otherwise disrupted skin (Drucker, 2012).

*Gentamicin.* Gentamicin is an aminoglycoside that inhibits protein synthesis by binding to the 30S subunit of bacterial ribosomes. It has activity for certain gram-positive bacteria, including *S. aureus*, and gram-negative bacteria, including *P. aeruginosa*. Gentamicin sulfate 0.1% cream or ointment may be applied three or four times daily to affected areas.

*Silver Sulfadiazine.* Silver sulfadiazine binds to bacterial DNA and inhibits replication. It is bactericidal against gram-positive bacteria, including MRSA, and gram-negative bacteria, including *P. aeruginosa*. Silver sulfadiazine is most frequently used in the treatment of partial-thickness burns or lower extremity venous stasis ulcers. However, recent studies have failed to demonstrate efficacy in these settings (Miller et al., 2012). Rarely, argyria has developed in patients using silver sulfadiazine over extensive areas of the body (Browne and Levy, 2008).

*Mafenide.* Mafenide acetate is a topical sulfonamide, although its mechanism of action may be distinct from other sulfonamides. Mafenide is approved as adjunctive therapy for burn wounds and is available as either an 85-mg/g cream or as a 5% topical solution supplied as 50-g packets of powder that must be reconstituted. It exerts broad bacteriostatic action against many gram-positive and gram-negative organisms, including *P. aeruginosa* and some anaerobes. The high solubility of mafenide allows it to diffuse easily through eschar and devascularized tissue, which is beneficial for treating subeschar burn wound infection. Mafenide and its metabolites inhibit carbonic anhydrase, so treated patients may be at risk for metabolic acidosis, especially if they have renal failure or if mafenide is applied to large surface areas. Other potential adverse effects include pain or burning sensation with application, facial edema, allergic contact dermatitis, and rarely hemolytic anemia in patients with G6PD deficiency.

**Systemic Therapy.** Deeper or complicated SSTIs typically require systemic administration of antimicrobials, which are also useful for superficial infections with diffuse involvement or that are not responding to topical therapy. Because SSTIs are most commonly caused by staphylococcal and staphylococcal species, penicillins (especially β-lactamase–resistant β-lactams) and cephalosporins are the systemic antibiotics used most frequently in their treatment. A growing concern is the increased incidence of SSTIs with hospital- and community-acquired MRSA and drug-resistant pneumococci. Common outpatient treatment options for MRSA include clindamycin, doxycycline, and trimethoprim-sulfamethoxazole. When coverage for both MRSA and streptococci is needed, clindamycin alone or the combination of either doxycycline or trimethoprim-sulfamethoxazole with a β-lactam may be used (Stevens et al., 2014). Clindamycin should not be used as empiric therapy if local resistance rates are greater than 10%–15% (Stevens et al., 2014). Treatment options for more severe or complicated SSTIs that provide coverage for MRSA include vancomycin, linezolid, quinupristin-dalfopristin, and daptomycin. More recent additions to this armamentarium include dalbavancin, oritavancin, telavancin, tedizolid, and ceftaroline.

**Antifungal Agents**

Fungal infections are amongst the most common causes of skin disease in the U.S., and numerous effective topical and oral antifungal agents have been developed. The pharmacology, uses, and toxicities of antifungal drugs are discussed in Chapter 61. This section addresses the management of common superficial cutaneous mycoses. Recommendations for cutaneous antifungal therapy are summarized in Table 70–7. Topical antifungal agents used for superficial mucocutaneous mycoses are listed in Table 70–8.

**Dermatophyte Infections of the Skin (Tinea Corporis, Cruris, and Pedis)**

The dermatophyte infections (tinea corporis, cruris, and pedis) generally respond to topical antifungals, including allylamines (naftifine, terbinafine); benzylamines (butenafine); azoles (econazole, luliconazole); and ciclopirox (Rotta et al., 2013). Allylamines and benzylamines may provide a more sustained clinical cure compared to azole antifungals (Rotta et al., 2013). Bacterial superinfection of tinea pedis can occur, and antifungal agents such as econazole and ciclopirox that also provide some bacterial coverage may be useful in those situations. Systemic therapy with terbinafine, fluconazole, itraconazole, or griseofulvin is used.

when there is more extensive cutaneous involvement or a poor response to topical therapy.

**Dermatophyte Infections of the Hair and Follicles**

Dermatophyte infections of the hair (tinea capitis) or follicularly based infections of the skin (Majocchi granuloma) require systemic therapy. Griseofulvin has been the traditional medication for tinea capitis, and treatment failure is often related to inadequate dosage or length of treatment. Terbinafine may be more effective for *Trichophyton tonsurans*, which is the most common cause of tinea capitis in the U.S. (Elewski et al., 2008). Fluconazole and itraconazole are also effective (Gupta and Paquet, 2013).

**Onychomycosis**

Onychomycosis is a fungal infection of the nails that is commonly caused by dermatophytes or candida. Onychomycosis is most effectively treated with systemic therapy (de Sa et al., 2014). Fungal infection should be confirmed prior to initiating oral therapy. There are other causes of nail dystrophy, and approximately one-third of nails with clinically suspected onychomycosis do not have fungal infection (Mehregan and Gee, 1999). Terbinafine is the most effective treatment of dermatophyte onychomycosis, with typical adult dosing of 250 mg daily for 6 weeks for fingernails and 12 weeks for toenails. Terbinafine remains in the nails for several weeks after medication administration has ceased, and some studies have utilized pulsed dosing of terbinafine 500 mg daily for 1 week per month for 3 months based on this finding. Itraconazole is another effective option for dermatophyte onychomycosis and is more effective than terbinafine for candidal onychomycosis. Itraconazole persists in the nail for 6–9 months after administration has ceased. Traditional adult dosing for itraconazole is 200 mg daily for 12 weeks; however, pulsed dosing is an alternative option because itraconazole of its long persistence after administration has ceased. Itraconazole pulsed dosing is 400 mg daily for 1 week per month for 2 months for fingernails and 3 months for toenails, which may be more effective than traditional dosing with fewer side effects. Fluconazole is an alternative option that may be useful in patients who cannot use terbinafine or itraconazole. Griseofulvin, used in the past, is less efficacious and requires much longer treatment courses; it is no longer a preferred option. Topical antifungals approved for onychomycosis include ciclopirox

**Cutaneous Candidiasis**

Cutaneous candidiasis is typically treated with topical azole antifungals or nystatin when localized. Systemic azole antifungals such as fluconazole or itraconazole may be needed for more recalcitrant or severe cases.

**Malassezia Infections**

*Pityrosarcomma versicolor* and *seborheic dermatitis* are caused by *Malassezia* (pityrosporum) species and are frequently treated with azole antifungals in cream or shampoo formulations. Topical ciclopirox and terbinafine are also approved for use. Additional topical therapies include selenium sul- fide, pyrithione zinc, sodium sulfacetamide, and sulfur with or without salicylic acid. Oral fluconazole or itraconazole are sometimes used for pityriasis versicolor when diffuse or resistant. Oral terbinafine does not reach adequate concentrations in the superficial stratum corneum to be effective.

**Antiviral Agents**

Viral infections of the skin by HPV, HSV, molluscum contagiosum virus, and VZV are common and produce a variety of lesions, including warts or blisters. Acyclovir, famciclovir, and valacyclovir are often used systemically to treat HSV and VZV infections (see Chapter 62). Cidofovir and foscarinet are useful for treating acyclovir-resistant HSV. Topically, acyclovir, docosanol, penciclovir, and combination acyclovir/hydrocortisone are available for treating mucocutaneous HSV; however, they are less effective than systemic therapies (Sarnoff, 2014). Acyclovir is also available as a 50-mg buccal tablet for herpes labialis to be applied as a single dose to the upper gum just above the incisor tooth within 1 h of prodromal symptoms.

Cidofovir is used off label topically or intraleosionally as treatment of anogenital warts caused by HPV. Topical cidofovir 1% gel or cream must be obtained through a compounding pharmacy. It is applied once daily for 5 consecutive days every other week for a maximum of six cycles. Additional treatments for genital warts are nonspecific cytodestructive or immunomodulatory therapies, which are discussed in further detail in other sections. Cytodestructive modalities include topical use of cryotherapy, podophyllin (podophyllum resin) or podoflox (podophyllotoxin), and trichloroacetic acid. Topical immunomodulatory therapies include imiquimod and sinecatechins. Also, intralesional or systemic interferons α, α′, and β may be useful for treating refractory or recurrent genital warts, but their use is limited by pain with multiple injections for intrale- sional use and by potential for severe side effects with systemic use (Smith et al., 2007).

**Agents Used to Treat Infestations**

Infestations with ectoparasites such as lice and scabies are common throughout the world. These conditions have a significant impact on public health in the form of disabling pruritus, secondary infection, and, in the case of the body louse, transmission of life-threatening illnesses such as typhus. Topical and oral medications are available to treat these infestations (Diamantis et al., 2009).

- **Permethrin** is a synthetic pyrethroid that interferes with insect Na+ transport proteins, causing neurotoxicity and paralysis. Resistance due to mutations in the transport protein has been reported and appears to be increasing. A 5% cream is available by prescription for the treatment of scabies, and a 1% lotion or cream rinse is available OTC for the treatment of lice. Permethrin is approved for use in infants 2 months or older. Other OTC agents used in the treatment of lice are pyrethrins plus piperonyl butoxide in various formulations and acetic acid plus isopropanol shampoo.

- **Lindane** is an organochloride compound that induces neuronal hyperstimulation and eventual paralysis of parasites. Due to several cases of neurotoxicity in humans, the FDA has labeled lindane as a second-line drug in treating pediculosis and scabies and has highlighted the...

</table>
potential for neurotoxicity in children and adults weighing less than 50 kg and patients with underlying skin disorders such as atopic dermatitis and psoriasis. Lindane is contraindicated in premature infants and patients with seizure disorders.

- **Malathion** is an organophosphate that inhibits acetylcholinesterase in lice, causing paralysis and death. It is approved for treatment of head lice in children 6 years and older. The current formulation of malathion lotion contains 78% isopropyl alcohol and is flammable. Detailed information on malathion’s actions and adverse effects may be found in Chapter 10.

- **Benzyl alcohol** 5% lotion is approved for the treatment of lice in patients 6 months and older. Benzyl alcohol inhibits lice from closing their respiratory spiracles, which allows the vehicle to obstruct the spiracles and causes the lice to asphyxiate. There may be less potential for development of resistance with this mechanism of action compared to traditional pesticides.

- **Ivermectin** is an anthelmintic drug (see Chapter 55) approved for oral treatment of onchocerciasis and Strongyloides. Recently, topical ivermectin 0.5% lotion was approved to treat lice in patients 6 months and older and 1% cream to treat rosacea. Ivermectin is also effective in the off-label treatment of scabies. Because ivermectin does not cross the human blood-brain barrier, there is no major CNS toxicity; minor CNS side effects with oral administration may include dizziness, somnolence, vertigo, and tremor. Topical administration may cause local irritant effects, such as conjunctivitis, eye irritation, dry skin, or skin-burning sensation, although these occurred in fewer than 1% of patients during clinical trials. For both scabies and lice, ivermectin typically is given at an oral dose of 200 μg/kg, which may be repeated in 1 week. In cases of crusted scabies, longer treatment cycles of oral ivermectin may be needed, sometimes in addition to topical keratolytics and scabicides (Ortega-Loayza et al., 2015). It is not recommended to use in children weighing less than 15 kg.

- **Spinosad** 0.9% topical suspension is approved for treatment of head lice in patients 6 months or older. Spinosad causes CNS excitation and involuntary muscle contractions, leading to insect paralysis and death.

  Less effective topical treatments for scabies and lice include 10% crotonitron cream and lotion and extemporaneously compounded 5%–10% precipitated sulfur in petrolatum. Precipitated sulfur may be useful for patients in whom other therapies are contraindicated or not approved; it is typically applied once daily for 3–5 consecutive days.

### Cytotoxic and Immunosuppressant Drugs

Cytotoxic and immunosuppressant drugs are used in dermatology for immunologically mediated diseases such as psoriasis, autoimmune blistering diseases, and leukocytoclastic vasculitis. See Table 70–9 for their mechanisms of action.

#### Antimetabolites

**Methotrexate** is used for moderate-to-severe psoriasis. It suppresses immunocompetent cells in the skin, and it also decreases the expression of CLA-positive T cells and endothelial cell E-selectin, which may account for its efficacy. Methotrexate is useful in treating a number of other dermatological conditions, including atopic dermatitis, pityriasis lichenoides et varioliformis, lymphomatoid papulosis, sarcoidosis, pemphigus vulgaris, pityriasis rubra pilaris, lupus erythematosus, dermatomyositis, and CTCL.

Methotrexate often is used in combination with phototherapy and photochemotherapy or other systemic agents. Widely used oral regimens include 10–25 mg once weekly as a single dose or as three divided doses given at 12-h intervals, with similar effectiveness using either regimen, or intramuscular administration of 10–25 mg injected once weekly (maximum of 30 mg/week) (Menter et al., 2009b).

Doses must be decreased for patients with impaired renal clearance. Methotrexate should not be administered with probenecid, trimethoprim-sulfamethoxazole, salicylates, or other drugs that can compete with it for protein binding and thereby raise plasma concentrations to levels that
Cyclophosphamide has many adverse effects (see Chapter 66), including the risk of secondary malignancy and myelosuppression, and is used only in the most severe, recalcitrant dermatological diseases. **Mechlorethamine hydrochloride** and **carmustine** are used topically to treat CTCL (Jawed et al., 2014). It is important to monitor CBCs and liver function tests because systemic absorption can cause bone marrow suppression and hepatitis. Other side effects include allergic contact dermatitis, irritant dermatitis, secondary cutaneous malignancies, and pigmentary changes. Carmustine also can cause erythema and posttreatment telangiectasias.

### Microtubule Inhibitors

**Vinblastine** is approved for systemic use in Kaposi sarcoma and advanced CTCL. Intralesional vinblastine also is used to treat Kaposi sarcoma (Regnier-Rosencher et al., 2013).

**Podophyllin (podophyllum resin)** is a mixture of chemicals from the plant *Podophyllum peltatum* (mandrake or May apple) that contains podophyllotoxin (podofilox), which binds to microtubules and causes mitotic arrest in metaphase (Fathi and Tsoukas, 2014). In the U.S., it must be obtained through a compounding pharmacy. Podophyllum resin 25% is applied topically by a physician and left in place for no longer than 2–6 h weekly for the treatment of anogenital warts. Irritation and ulcerative local reactions are the major side effects. It should not be used in the mouth or during pregnancy. It is recommended that the use of provider-administered podophyllin resin be replaced by the purified podophyllotoxin (podofilox) for patient-administered use. Podofilox is available as a 0.5% gel or solution for at-home application two times daily for 3 consecutive days, repeated weekly as needed for up to four cycles.

### Other Cytotoxic Agents

**Bleomycin** is used off label intralesionally for palliative treatment of squamous cell carcinoma and recalcitrant warts and has cytotoxic and pro-inflammatory effects. Intralesional injection of bleomycin into the digits has been associated with a vasospastic response that mimics Reynaud phenomenon. Other potential adverse reactions include local skin necrosis and flagellate hyperpigmentation. Systemic bleomycin has been used off label for Kaposi sarcoma (see Chapter 66) (Regnier-Rosencher et al., 2013).

**Liposomal anthracyclines** (specifically doxorubicin) may provide first-line monotherapy for advanced Kaposi sarcoma (Regnier-Rosencher et al., 2013).

**Inogen melubate** gel, an extract from the plant *Euphorbia peplus*, is FDA approved for actinic keratosis (Micali et al., 2014). In experimental studies, it was reported to rapidly cause mitochondrial swelling and apoptosis of dysplastic keratinocytes. The gel is applied once daily for 2–3 consecutive days. Adverse effects may include local skin irritation, pain, pruritus, and infection at application site; periorbital edema; nasopharyngitis; and headache. Cases of allergic contact dermatitis and reactivation of herpes zoster have been reported.

### Azathioprine and Mycophenolate Mofetil

**Azathioprine** is discussed in Chapter 35. In dermatological practice, the drug is used off label as a steroid-sparing agent for autoimmune and inflammatory dermatoses, including pemphigus vulgaris, bullous pemphigoid, dermatomyositis, atop dermatitis, chronic actinic dermatitis, lupos erythematosus, psoriasis, pyoderma gangrenosum, and Behçet disease.

Azathioprine is cleaved to 6MP, which in turn is converted to additional metabolites that inhibit de novo purine synthesis (see Figure 51–5 and Chapter 66). The level of thiopurine methyltransferase (TPMT) enzyme activity should be measured before initiating azathioprine therapy because low levels of TPMT activity are associated with increased drug toxicity (see Chapter 66). In general, the starting dosage is 1–2 mg/kg/d. Careful laboratory monitoring is important, especially in those with diminished TPMT activity.

**Mycophenolate mofetil** and mycophenolate sodium are immunosuppressants approved for prophylaxis of organ rejection in patients with

*Other uses include treatment of pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, paraneoplastic pemphigus, pyoderma gangrenosum, toxic epidermal necrolysis, Wegener granulomatosis, polyarteritis nodosa, Churg-Strauss angitis, Behçet disease, scleromyxedema, and cytophagic histiocytic panniculitis. The usual oral dosage is 2–2.5 mg/kg/d in divided doses, and there often is a 4- to 6-week delay in onset of action (Meurer, 2012). Alternatively, intravenous pulse administration of cyclophosphamide may offer advantages, including lower cumulative dose and a decreased risk of bladder cancer.*
renal, cardiac, and hepatic transplants (see Chapter 35). Mycophenolate mofetil is a prodrug that is hydrolyzed to mycophenolic acid by plasma esterases; the salt of the acid, mycophenolate sodium, is available in an enterico-coated formulation. Mycophenolic acid functions as a specific inhibitor of T- and B-lymphocyte activation and proliferation through inhibition of inosine monophosphate dehydrogenase, thereby reducing GMP synthesis by the de novo purine synthetic pathway. Lymphocytes are vulnerable due to their lack of the salvage pathway for purine synthesis. The drug also may enhance apoptosis.

Mycophenolate mofetil is used off-label increasingly to treat inflammatory and autoimmune diseases in dermatology; dosages typically range from 2 to 3 g/ d orally in adults or 30–50 mg/kg/d in pediatric patients, given in divided doses twice daily. This agent is particularly useful as a corticosteroid-sparing agent in the treatment of autoimmune blistering disorders and has been used effectively in the treatment of inflammatory diseases such as psoriasis, atopc dermatitis, and pyoderma gangrenosum. Isolated cases of PML and pure red cell aplasia have been reported in solid organ transplant patients receiving mycophenolate mofetil. The most common side effects of mycophenolate mofetil are dose-dependent GI symptoms (e.g., diarrhea, nausea, and abdominal pain). Enteric-coated mycophenolate sodium improves GI tolerability; the enteric coating delays absorption until the medication reaches the small intestine rather than occurring in the stomach.

Calcineurin Inhibitors

The mechanisms of action and clinical pharmacology of calcineurin inhibitors are described in Chapter 35, and Figure 35–2 shows their main molecular effects as immunosuppressants. Cyclosporine is a potent immunosuppressant isolated from the fungus Tolypocladium inflatum. Cyclosporine is FDA approved for the treatment of psoriasis. A modified microemulsion formulation has increased bioavailability and more consistent absorption than the original formulation. Other cutaneous disorders that typically respond well to cyclosporine are atopic dermatitis, alopecia areata, epidermolysis bullosa acquisita, pemphigus vulgaris, bullous pemphigoid, lichen planus, and pyoderma gangrenosum. The usual oral dosage of the modified formulation is 2.5 to 5 mg/kg/d, often given in two divided doses (Menter et al., 2009b; Sidbury et al., 2014).

Hypertension and renal dysfunction are the major adverse effects associated with the use of cyclosporine. These risks can be minimized by monitoring serum creatinine (which should not rise more than 30% above baseline), calculating creatinine clearance or glomerular filtration rate in patients on long-term therapy or with a rising creatinine, maintaining a daily dose of less than 5 mg/kg, and regularly monitoring blood pressure. Alternation with other therapeutic modalities may diminish cyclosporine toxicity. Patients with psoriasis who are treated with cyclosporine are at increased risk of cutaneous, solid organ, and lymphoproliferative malignancies. The risk of cutaneous malignancies is compounded in patients who have received phototherapy with PUVA.

Tacrolimus is available in a topical form for the treatment of skin disease and also is marketed in oral and injectable formulations. Systemic tacrolimus has shown some efficacy in the off-label treatment of inflammatory skin diseases such as psoriasis, pyoderma gangrenosum, and Behçet disease. When tacrolimus is administered systemically, the most common side effects are hypertension, nephrotoxicity, neurotoxicity, GI symptoms, hyperglycemia, and hyperlipidemia.

Topical formulations (0.03% and 0.1%) of tacrolimus ointment are approved for the treatment of atopic dermatitis in adults and in children 2 years or older for 0.03% ointment and 16 years or older 0.1% ointment. Other uses include for treatment of intertriginous psoriasis, vitiligo, mucosal lichen planus, graft-versus-host disease, allergic contact dermatitis, and rosacea. Ointment is applied to the affected area two times daily and generally is well tolerated. Common side effects at the site of application are transient erythema, burning, and pruritus. Other adverse effects include skin tingling, flu-like symptoms, headache, alcohol intolerance, folliculitis, acne, and hyperesthesia. Systemic absorption generally is very low and decreases with resolution of the dermatitis. Topical tacrolimus should be used with extreme caution in patients with Netherton syndrome; these patients may develop elevated blood levels of the drug after topical application (Eichenfield et al., 2014).

Pimecrolimus (as a 1% cream) is approved for the treatment of atopic dermatitis in patients 2 years and older. Its mechanism of action and side-effect profile are similar to those of tacrolimus. It has low-to-negligible systemic absorption after topical application. Tacrolimus and pimecrolimus are approved as second-line agents for short-term and intermittent treatment of atopic dermatitis in patients unresponsive to, or intolerant of, other treatments. Unlike topical corticosteroids, they do not carry the risk of skin atrophy and may be especially useful as steroid-sparing agents or for use on sensitive skin sites (e.g., eyelids, face, skin folds) or areas with steroid-induced atrophy.

mTor Inhibitors

Sirolimus causes immunosuppressive and antiproliferative effects through inhibition of mTOR as part of the PI3 kinase/Akt/mTOR pathway (see Figures 3–16, 35–2, and 67–4). The mTOR inhibitors are established treatments for posttransplant immunosuppression (Chapter 35) and as antineoplastic agents for malignancies such as renal and hepatocellular carcinoma (Chapter 67). Off-label use of mTOR inhibitors in dermatology includes the treatment of tuberous sclerosis complex, pachyonychia congenita, complex vascular anomalies, and inflammatory dermatoses such as systemic sclerosis (Fogel et al., 2015). Systemic mTOR inhibitors may be associated with several side effects, with dermatologic side effects amongst the most common, including stomatitis, mucositis, inflammatory cutaneous eruptions, and nail changes such as paronychia (Fogel et al., 2015). Topical formulations have been used to decrease the risk of side effects associated with systemic therapy. Newer semisynthetic analogues of sirolimus such as everolimus and temsirolimus are available and have improved water solubility and efficacy.

Immunomodulators and Anti-inflammatory Agents

Imiquimod exerts immunomodulatory effects by acting as a ligand at toll-like receptors in the immune system and inducing the cytokines IFN-α, TNF-α, and IL-1, IL-6, IL-8, IL-10, and IL-12. Imiquimod cream is available in 2.5%, 3.75%, and 5% strengths. Approved for the treatment of genital warts, imiquimod 5% cream is applied to genital or perianal lesions three times a week until resolution of warts or up to a 16-week period (and repeated as necessary) (Pathi and Tsoukas, 2014). Imiquimod also is approved for the treatment of actinic keratoses, with various regimens used (Micali et al., 2014). No more than 36 single-use packets per 16-week course of therapy should be prescribed for actinic keratoses. The 5% cream is also FDA approved for the treatment of superficial BCCs at a dosage of five applications/week for 6 weeks. Off-label applications include the treatment of nongenital warts, molluscum contagiosum, extraanammary Paget disease, and Bowen disease. Irritant reactions occur in virtually all patients; the degree of inflammation parallels therapeutic efficacy.

Sinecachexins are partially purified green tea extracts containing a mixture of 85%–95% catechins and other green tea components. They are approved for the topical treatment of external genital and perianal warts in immunocompetent patients more than 18 years of age. The mechanism of action is unclear but may include a combination of antioxidant, antiviral, antiangiogenic, proapoptotic, and immunomodulatory activities. The sinecachexin 15% ointment is applied three times daily for up to 16 weeks until clearance of the warts. The most common side effects are local skin reactions, including erythema, pruritus or burning, pain, superficial ulceration, and edema, with the intensity of local reactions peaking between 2 and 4 weeks of use. Local site reactions may be indicative of a positive clinical response, and patients are encouraged to treat through them as tolerated.

Dapsone is used in dermatology for its anti-inflammatory properties, particularly in sterile (noninfectious) pustular diseases of the skin (Zhu et al., 2015). Mycophenolate mofetil is used off label increasingly to treat inflammatory and autoimmune diseases such as psoriasis, atopic dermatitis, and pyoderma gangrenosum. No more than 36 single-use packets per 16-week course of therapy should be prescribed for actinic keratoses. The 5% cream is also FDA approved for the treatment of superficial BCCs at a dosage of five applications/week for 6 weeks. Off-label applications include the treatment of nongenital warts, molluscum contagiosum, extraanammary Paget disease, and Bowen disease. Irritant reactions occur in virtually all patients; the degree of inflammation parallels therapeutic efficacy.
Dapsone prevents the respiratory burst from myeloperoxidase, suppresses neutrophil migration by blocking integrin-mediated adherence, inhibits adherence of antibodies to neutrophils, and decreases the release of eicosanoids and blocks their inflammatory effects. Dapsone is discussed further in Chapter 60.

Dapsone is approved for oral use in dermatitis herpetiformis and leprosy and for topical use in acne vulgaris. It is also particularly useful in the off-label treatment of linear IgA dermatosis, bullous systemic lupus erythematosus, erythema elevatum diutinum, and subcorneal pustular dermatosis. In addition, reports indicate efficacy in patients with acne fulminans, pustular psoriasis, lichen planus, Hailey-Hailey disease, pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, leukocytoclastic vasculitis, Sweet syndrome, granuloma faciale, relapsing polychondritis, dermatitis herpetiformis, bullous pemphigoid, cicatricial pemphigoid, leukocytoclastic vasculitis, Behçet disease, urticarial vasculitis, pyoderma gangrenosum, and granuloma annulare.

The initial oral dosage is 50 mg/d, followed by increases of 25 mg/d at weekly intervals, titrated to the minimal dosage necessary for effect. Potential side effects of dapsone include methemoglobinemia and hemolysis (G6PD level should be checked in all patients). The H2 blocker cimetidine inhibits numerous CYPs and thereby reduces the N-hydroxylation of dapsone to the hydroxylamine metabolite that causes the methemoglobinemia. Other toxicities of dapsone include agranulocytosis, peripheral neuropathy, and psychosis.

*Thalidomide* is an anti-inflammatory, immunomodulatory, and antiangiogenic agent experiencing resurgence in the treatment of dermatological diseases (Wu et al., 2005). For details of its actions, see Chapter 36 under Immunostimulants and Figure 66–2 and associated text.

Thalidomide is FDA approved for the treatment of erythema nodosum leprosum. Reports also suggest its efficacy in actinic prurigo, aphiophous stomatitis, Behçet disease, Kaposis sarcoma, the cutaneous manifestations of lupus erythematosus, and prurigo nodularis and uremic prurigo. Thalidomide has been associated with increased mortality when used to treat toxic epidermal necrolysis. In utero exposure can cause limb abnormalities (phocomelia), as well as other congenital anomalies. *Thalidomide should never be taken by women who are pregnant or who could become pregnant while taking the drug. It also may cause an irreversible neuropathy. Because of its teratogenic effects, thalidomide use is restricted and requires both pharmacists and physicians to register in a risk evaluation and mitigation strategy (REMS) program. Newer analogues of thalidomide are available, including lenalidomide and pomalidomide.*

**Targeted Immunotherapies for Psoriasis and Atopic Dermatitis**

Targeted immunotherapies, including biological agents, are rapidly evolving for the treatment of psoriasis, as the underlying pathogenesis is better understood (Table 70–10). In addition, biological therapy for atopic dermatitis is on the horizon. The appeal of these targeted therapies is that they specifically target the activities of T lymphocytes and cytokines that mediate inflammation, whereas traditional systemic therapies are broadly immunosuppressive or cytotoxic. The pathogenesis of psoriasis and atopic dermatitis is discussed briefly next, followed by the relevant targeted therapies. Targeted therapies are discussed in further detail in Chapter 35.

Psoriasis is a chronic immune-mediated inflammatory disorder involving the innate and adaptive immune systems, with resultant abnormal keratinocyte proliferation (Figure 70–3). Psoriasis is not limited to the skin, as there can be psoriatic arthritis and other systemic manifestations. Previously thought to be primarily Th1 mediated, more recent developments demonstrate that the Th17/IL-17 pathway plays the most significant role (Girolomoni et al., 2012). Mediators of inflammation, such as IL-23, TNF-α, and IL-17 are key targets for therapy (Girolomoni et al., 2012; Sobell and Leonardi, 2014). In addition, therapies such as inhibitors of Jak and cyclic nucleotide PDEs) are useful to decrease expression or signal transduction of inflammatory cytokines (Sobell and Leonardi, 2014).

*No embryo-fetal toxicity in mice and non-human primates; no adequate, well controlled studies in pregnant women; use only if benefit justifies potential risk to fetus.*
Atopic dermatitis is a chronic skin disorder characterized by epidermal barrier dysfunction and immune-mediated inflammation. Patients often develop asthma and allergic rhinitis as well. Acute atopic dermatitis is Th2 cell mediated, associated with cytokines IL-4, IL-5, and IL-13, while chronic atopic dermatitis also involves Th1 cell-mediated activity, associated with cytokines IL-12 and IFN-γ. Topical corticosteroids and calcineurin inhibitors are common therapies, and several of the traditional immunosuppressants have been used for more severe or resistant cases (Eichenfeld et al., 2014; Sidbury et al., 2014). Targeted therapies show promise for the future treatment of atopic dermatitis (Beck et al., 2014).

Tumor Necrosis Factor Inhibitors

Blockade of TNF-α reduces inflammation, decreases keratinocyte proliferation, and decreases vascular adhesion, resulting in improvement in psoriatic lesions. Because TNF-α inhibitors alter immune responses, patients on all anti-TNF-α agents are at increased risk for serious infection and for malignancies. Other adverse events include exacerbation of congestive heart failure and demyelinating disease in predisposed patients. All patients should be screened for tuberculosis, history of demyelinating disorder, cardiac failure, active infection, or malignancy prior to therapy. TNF-α inhibitors include monoclonal antibodies directed against TNF-α (adalimumab, infliximab) or a soluble TNF receptor that can bind TNF-α (etanercept) (see Chapter 35). All TNF-α inhibitors are able to bind both soluble and membrane-bound TNF, but the monoclonal antibodies against TNF-α with an IgG, Fc portion are also able to activate complement-dependent cytotoxicity on binding of membrane-bound TNF-α. This may explain the increased efficacy of these agents in comparison to etanercept for treating granulomatous conditions as well as the higher risk of infection with their use.

Etanercept is a soluble, recombinant, fully human TNF receptor fusion protein consisting of two molecules of the ligand-binding portion of the TNF receptor (p75) fused to the Fc portion of IgG1. It binds both TNF-α and TNF-β. Etanercept is approved for plaque psoriasis and psoriatic arthritis in adults. Studies have shown etanercept to be safe and efficacious for pediatric psoriasis at dosing of 0.8 mg/kg (maximum 50 mg) once weekly (Bellobi Schmidt and Shah, 2015).

Infliximab, a mouse-human chimeric IgG1, monoclonal antibody directed against human TNF-α, is approved for treatment of chronic severe plaque psoriasis and psoriatic arthritis. The administration of infliximab via intravenous infusion can be a limiting factor; however, compared to other TNF-α inhibitors, its onset of action may be faster and efficacy greater. Neutralizing antibodies to infliximab may develop and lead to decreased efficacy over time. Concomitant administration of methotrexate or glucocorticoids may suppress this neutralizing antibody formation.

Adalimumab is a human IgG1 monoclonal antibody directed against TNF-α; thus, the risk for development of neutralizing antibodies is reduced compared to infliximab. Adalimumab is approved for treatment of plaque psoriasis and psoriatic arthritis in adults. Safety of adalimumab in pediatric patients for psoriasis is supported by its use in other conditions, such as juvenile idiopathic arthritis (Bellodi Schmidt and Shah, 2015). Adalimumab is also approved for treatment of hidradenitis suppurativa.

Golimumab and certolizumab pegol are TNF-α inhibitors that are currently approved for psoriatic arthritis but not psoriasis. However, studies of these medications for psoriatic arthritis also demonstrated improvement of plaque psoriasis, and a phase III trial of certolizumab pegol for plaque psoriasis demonstrated efficacy. Golimumab is a fully human monoclonal antibody against TNF-α with a longer t1/2 than other TNF-α inhibitors. Certolizumab pegol is a pegylated Fab fragment of a human monoclonal antibody against TNF-α. Because certolizumab pegol lacks the Fc portion, it is not able to activate complement-mediated cytotoxicity.

IL-12/23 Inhibitors

Ustekinumab is a human IgG1 monoclonal antibody directed against the common p40 subunit of IL-12 and IL-23. IL-12 promotes Th1 activity and related TNF-α and IFN-γ production, while IL-23 activates Th17 cells that produce IL-17A, which regulates tissue inflammation and autoimmune responses. Ustekinumab is approved for treatment of moderate-to-severe plaque psoriasis and psoriatic arthritis. After initial doses at weeks 0 and 4, it is administered every 12 weeks for the maintenance phase of therapy, which may be ideal for some patients. Studies have shown ustekinumab to be safe and efficacious in adolescent patients at the same dosing as adults (Bellobi Schmidt and Shah, 2015).

IL-17 Inhibitors

Keratinocytes are the major target for IL-17 in psoriasis, with IL-17 stimulation causing increased keratinocyte expression of inflammatory cytokines and other effects that contribute to epidermal hyperproliferation and barrier dysfunction. Clinical trials have demonstrated that IL-17 inhibitors are very efficacious for plaque psoriasis.

Secukinumab is a fully human IgG1κ monoclonal antibody against IL-17A approved for the treatment of moderate-to-severe plaque psoriasis in adults. Additional IL-17 inhibitors in phase III clinical trials include ixekizumab, a humanized IgG1 monoclonal antibody against IL-17A, and brodalumab, a human monoclonal antibody against the IL-17 receptor.
1288 (anti-IL-17RA), which prevents binding and activity of IL-17. The most common adverse effects for IL-17 inhibitors are nasopharyngitis, upper respiratory tract infection, and diarrhea. There is the potential for increased mucocutaneous candidiasis infections, although this was not common during clinical trials.

**PDE4 Inhibitors**

Apremilast is an oral PDE4 inhibitor that increases intracellular cyclic AMP levels, thereby decreasing expression of inflammatory cytokines such as TNF-α and IL-23 and increasing expression of anti-inflammatory cytokines such as IL-10. Apremilast is approved for treatment of moderate-to-severe plaque psoriasis and psoriatic arthritis in adults. It has also shown efficacy for atopic dermatitis in a pilot study. The most common side effects are weight loss and depression.

**Jak Inhibitors**

Janus kinases are tyrosine kinases involved in cytokine receptor signaling, and Jak inhibition leads to decreased downstream activity of STAT, which modulates transcription of genes involved in cell growth, proliferation, and differentiation. Tofacitinib is an oral Jak inhibitor approved for use in rheumatoid arthritis in adults. It has demonstrated efficacy for psoriasis in clinical trials and for atopic dermatitis in a pilot study.

**IL-4 Inhibitors**

**Duliquidam** is a fully human monoclonal antibody against the alpha subunit of IL-4R that inhibits both IL-4 and IL-13 signaling as they each exert their action through binding an IL-4Ra/IL-13Ra1 receptor complex (Beck et al., 2014). IL-4 and IL-13 are important mediators of the Th2 immune response that is involved in acute atopic dermatitis. Duliquidam has shown promising results in clinical trials, demonstrating significant improvement in disease severity and fewer skin infections compared to placebo (Beck et al., 2014). The most frequent adverse effects are nasopharyngitis and headache.

**Intravenous Immunoglobulin**

Intravenous immunoglobulin is prepared from fractionated pooled human sera derived from thousands of donors with various antigenic exposures (see Chapter 36). Preparations of IVIG are composed of more than 90% IgG, with minimal amounts of IgA, soluble CD4, CD8, HLA molecules, and cytokines. In dermatology, IVIG is used off label as an adjuvant or rescue therapy for autoimmune bullous diseases, toxic epidermal necrolysis, connective tissue diseases, vasculitis, urticaria, atopic dermatitis, and graft-versus-host disease (Smith et al., 2007).

Although the mechanism of action of IVIG is not understood fully, proposed mechanisms include suppression of IgG production, accelerated catabolism of IgG, neutralization of complement-mediated reactions, neutralization of pathogenic antibodies, downregulation of inflammatory cytokines, inhibition of autoreactive T lymphocytes, inhibition of immune cell trafficking, and blockage of Fas-ligand/Fas-receptor interactions (Smith et al., 2007). IVIG is contraindicated in patients with severe selective IgA deficiency (IgA ≤ 0.05 g/L). These patients may possess anti-IgA antibodies that place them at risk for severe anaphylactic reactions. Other relative contraindications include congestive heart failure and renal failure.

**Targeted Antineoplastic Agents**

Recent advances in understanding the molecular pathways and genetic alterations underlying cancer development have allowed for the rapid emergence of oncotherapeutic agents targeted against the specific molecules involved in tumor pathogenesis (Iwasaki et al., 2012; Jawed et al., 2014; John and Cowey, 2015). They are often better tolerated than conventional chemotherapeutic medications; however, adverse effects do still occur, with cutaneous toxicities amongst the most common. These therapies are discussed in further detail in Chapter 67.

**Targeted Therapies for Basal Cell Carcinoma**

Basal cell carcinoma is the most common malignancy in humans, and exposure to UV radiation plays a large role in its development, with intermittent, intense exposure increasing risk more than cumulative exposure. Some genetic disorders, such as nevoid BCC syndrome, predispose to BCC development as well. Typically, BCCs exhibit an indolent growth pattern with local invasion and tissue destruction over time, but metastasis is extremely rare. Nearly all BCCs have aberrant hedgehog pathway signaling, which leads to persistent activation and uncontrolled proliferation of basal cells (Iwasaki et al., 2012).

**Vismodegib and sonidegib** are smoothened inhibitors, which block activation of the hedgehog pathway (Iwasaki et al., 2012). They are approved for use in patients with locally advanced, metastatic, or recurrent disease that cannot be adequately managed with surgery or radiation therapy. They have also been used in patients with nevoid BCC syndrome. The most common side effects are muscle spasms, dysgeusia, alopecia, and diarrhea. The hedgehog pathway is vital to normal fetal development, so extreme caution is needed in women of reproductive potential, and men should be cautioned regarding potential for exposure and fetal harm through semen.

**Targeted Therapies for Cutaneous T-Cell Lymphoma**

**Denileukin difitox** is a fusion protein composed of diphtheria toxin fragments A and B linked to the receptor-binding portion of IL-2. It is approved for treatment of advanced CTCL in patients with more than 20% T cells expressing the surface marker CD25 (a subunit of the IL-2R), but it is not currently commercially available (Jawed et al., 2014).

The IL-2R is present on malignant and activated T cells but not resting B and T cells. Following binding to the IL-2R, denileukin difitox is internalized by endocytosis. The active fragment of diphtheria toxin is then released into the cytosol, where it inhibits protein synthesis via ADP ribosylation of elongation factor-2 (EF-2), leading to cell death. The response rate is 30%. Adverse effects include pain, fevers, chills, nausea, vomiting, and diarrhea; immediate hypersensitivity reaction in 60% of patients; and capillary leak syndrome in 20%–30% of patients.

**Histone deacetylase inhibitors** approved for treatment of progressive, persistent, or recurrent CTCL refractory to other systemic therapies include vorinostat and romidepsin. The exact mechanism of antineoplastic effect is not fully characterized; however, inhibition of HDAC may result in expression of tumor suppressor or cell cycle regulatory genes with resultant cell cycle arrest, differentiation, and apoptosis of cancer cells (Jawed et al., 2014). The partial response rate is approximately 30%–35%, with uncommon complete response. The most common side effects are GI symptoms, fatigue, and hematologic abnormalities.

**Alemtuzumab** is a humanized monoclonal antibody directed against CD52, which is found on immune cells, including T and B cells. Binding of alemtuzumab to CD52 causes neutrophil-mediated, antibody-dependent cellular toxicity (Jawed et al., 2014). It has been effectively used off label for CTCL and may be a secondary treatment option for patients with CTCL refractory to other therapies. It is commonly associated with infusion reactions and causes prolonged immunosuppression. Early studies reported opportunistic infections, so antimicrobial prophylaxis is recommended.

**Targeted Therapies for Melanoma**

Until recently, therapies for metastatic melanoma had low response rates along with either high toxicity or no effect on long-term survival. There has been rapid development of several new therapeutic options for metastatic or unresectable melanoma, primarily geared toward inhibition of mutated, abnormally activated tyrosine kinases that drive growth or enhancing immune function to combat malignant cells by...
Drugs for Hyperkeratotic Disorders

Keratolytic agents reduce hyperkeratosis through myriad mechanisms (e.g., breaking of intercellular junctions, increasing stratum corneum water content, increasing desquamation). Common disorders treated with keratolytics include psoriasis, seborrheic dermatitis, xerosis, ichthyoses, and verruca.

**α-Hydroxy acids** can reduce the thickness of the stratum corneum by solubilizing components of the desmosome, activating endogenous hydro-lytic enzymes, and drawing water into the stratum corneum, thereby facilitating cell separation. They also appear to increase glycosaminoglycans, collagen, and elastic fibers in the dermis and are used in various formulations to reverse photoaging. The FDA requires that cosmetics containing α-hydroxy acids be labeled with a sunburn alert warning that the product may increase sensitivity to the sun. α-Hydroxy acids used include glycolic, lactic, malic, citric, hydroxycaprylic, hydroxycapric, and mandelic.

**Salicylic acid** functions through solubilization of intercellular “cement,” reducing keratinocyte adhesion, and softening the stratum corneum. Salicylic acid may occur with widespread and prolonged use, especially in children and patients with renal or hepatic impairment. Salicylate toxicity has been reported with application of as little as 1%-2% salicylic acid in neonates when applied multiple times per day over a large body surface area (Madan and Levitt, 2014). Salicylic acid, while chemically not a true β-hydroxy acid, often is listed as such on cosmetic labels. Other β-hydroxy acid ingredients in cosmetics include β-hydroxybutanoic acid, δ-tropic acid, and trethocanic acid. Sun protection should accompany the topical application of these agents.

**Urea**, at low concentrations, increases skin absorption and retention of water, leading to increased flexibility and softness of the skin. At concentrations greater than 40%, urea denatures and dissolves proteins and is used to dissolve calluses or avulse dystrophic nails.

**Sulfur** is keratolytic, antisepctic, antiparasitic, and antiseborrheic. It exerts its keratolytic effect by reacting with cysteine within keratinocytes, producing cystine and hydrogen sulfide (H₂S). H₂S breaks down keratin, causing dissolution of the stratum corneum.

**Propylene glycol** (as 60%-100% aqueous solutions) increases the water content of the stratum corneum and enhances desquamation. It is most effective in disorders with retention hyperkeratosis.

### Drugs Affecting Hair Growth

#### Androgenic Alopecia

Androgenetic alopecia, commonly known as male and female pattern baldness, is the most common cause of hair loss in adults older than 40 years. The frequency and severity increase with age and may begin during puberty in some patients. It is a genetically inherited trait with variable expression. In susceptible hair follicles, dihydrotestosterone (DHT) binds to the androgen receptor, and the hormone-receptor complex activates the genes responsible for the gradual transformation of large terminal follicles into miniaturized vellus follicles. Treatment of androgenetic alopecia is aimed at reducing hair loss and maintaining existing hair (Varothai and Bergfeld, 2014).

**Minoxidil**, originally developed as an antihypertensive agent (see Chapter 28), was noted to be associated with hypertrichosis in some patients. Topical minoxidil is available as a 2% solution and a 5% solution or foam. Minoxidil enhances follicular size, resulting in thicker hair shafts, and stimulates and prolongs the anagen phase of the hair cycle, resulting in longer and increased numbers of hair. Treatment must be continued or any drug-induced hair growth will be lost. Allergic and irritant contact dermatitis can occur, and care should be taken in applying the drug because hair growth may emerge in undesirable locations. This is reversible on stopping the drug. Patients should be instructed to wash their hands after applying minoxidil. Patients with increased sulfo transferase enzyme activity are most likely to respond to minoxidil treatment; this may be a useful predictive test in the future (Roberts et al., 2014).

</tbody>
</table>
Finasteride inhibits the type II isozyme of 5α-reductase, the enzyme that converts testosterone to DHT (see Figure 45–3) and that is found in hair follicles. Balding areas of the scalp are associated with increased DHT levels and smaller hair follicles than nonbalding areas. Orally administered finasteride (1 mg/d) variably increases hair growth in men over a 2-year period. Finasteride is approved for use only in men but has been used off label for female pattern hair loss (Varothai and Bergfeld, 2014). Finasteride use in women is limited by its teratogenicity. Pregnant women should not be exposed to the drug because of the potential for inducing genital abnormalities in male fetuses. Adverse effects of finasteride include decreased libido, erectile dysfunction, ejaculation disorder, and decreased ejaculate volume. There have been postmarketing surveillance reports of persistent sexual dysfunction after stopping the medication. As with minoxidil, new hair growth will be lost when finasteride is discontinued. Dutasteride (0.5 mg/day) is a combined type I and type II isozyme 5α-reductase inhibitor that has similar or greater efficacy, but side effects may be more common (Varothai and Bergfeld, 2014).

Spironolactone is an aldosterone antagonist and K+-sparing diuretic; it also has antianrogen activity. It is used off label for female pattern alopecia at dosages of 50–200 mg/d (Varothai and Bergfeld, 2014). Women of reproductive potential should not receive spironolactone without reliable contraception because spironolactone can cause feminization of a male fetus.

Other Agents

Eflornithine is an ornithine decarboxylase (ODC) inhibitor approved for the reduction of excessive and unwanted facial hair in women. ODC is the rate-limiting enzyme in the synthesis of polyamines, which are important in cellular migration, differentiation, and proliferation. Levels of ODC activity are higher in proliferating cells, such as in follicular matrix cells in anagen phase, and inhibiting ODC decreases hair growth. Eflornithine 13.9% cream is applied twice daily and is intended to be used along with the patient’s preferred hair removal method to slow hair regrowth.

Bimatoprost is a prostaglandin analogue approved for topical treatment of hypotrichosis of the eyelashes by increasing their growth, including length, thickness, and darkness. The prostaglandin-mediated increase in eyelash growth was serendipitously noted during the use of intraocular prostaglandin analogues for glaucoma. The proposed mechanism of eye-lash growth is by an increase in the fraction of hairs in, and the duration of, the anagen phase. Increased pigmentation of the hairs is thought to occur due to stimulation of melanin production without an increase in the number of melanocytes. Importantly, brown pigmentation of the iris and eyelid skin may occur, and the increased iris pigmentation may be permanent.

### Treatment of Hyperpigmentation

The agents discussed are most effective on hormonally or light-induced pigmentation within the epidermis. They have limited efficacy on postinflammatory pigmentation within the dermis. Sun protection or avoidance is a vital component of any treatment regimen (Sheth and Pandya, 2011).

Hydroquinone (1,4-dihydroxybenzene) decreases melanocyte pigment production by inhibiting tyrosinase, the initial enzyme in the melanin biosynthetic pathway. In addition, it causes degradation of melanosomes and destruction of melanocytes by production of reactive oxygen radicals. Formulations containing 1.5%–2% hydroquinone are available OTC; 3%–4% hydroquinone formulations are available by prescription. Penetration enhancers and sunscreen ingredients are added to some formulations. A combination prescription product consisting of hydroquinone 4%, fluocinolone 0.01%, and tretinoin 0.05% is available. Adverse effects may include dermatitis and ochronosis.

Azelaic acid, a dicarboxylic acid isolated from cultures of Malassezia furfur, inhibits tyrosinase activity but is less effective than hydroquinone. Because it has mild comedolytic, antimicrobial, and anti-inflammatory properties, it also is often used in acne and papulopustular rosacea, especially in patients with postinflammatory hyperpigmentation.

Mequinol (4-hydroxyanisole) is a competitive inhibitor of tyrosinase. It was approved as a 2% prescription product in combination with 0.01% tretinoin and vitamin C for skin lightening, but it is not currently commercially available.

Monobenzene (monobenzyl ether of hydroquinone) causes permanent depigmentation and should not be used for routine hormonally induced or postinflammatory hyperpigmentation. A 20% cream is approved for final depigmentation therapy of extensive vitiligo affecting at least more than 50% body surface area; it is rarely used and not currently commercially available.

Glycolic acid is an α-hydroxy acid used in chemical peels for disorders of pigmentation. It is thought to work by inhibiting tyrosinase in a pH-independent manner and to cause exfoliation by decreasing keratinocyte adhesion. Potential side effects are erythema, desquamation, and postinflammatory hyperpigmentation. Glycolic acid peels are best used as adjunctive therapy along with other topical therapy in patients with refractory epidermal hyperpigmentation (Sheth and Pandya, 2011).

### Miscellaneous Agents

Capsaicin is an alkaloid derived from plants of the Solanaceae family (e.g., hot chilli peppers). Capsaicin interacts with the transient receptor potential vanilloid (TRPV1) receptor on C-fiber sensory neurons. TRPV1 is a ligand-gated nonselective cation channel of the TRP family, modulated by a variety of noxious stimuli. Chronic exposure to capsaicin first stimulates and then desensitizes this channel to capsaicin and diverse other noxious stimuli. Capsaicin also causes local depletion of substance P, an endogenous neuropeptide involved in sensory perception and pain transmission. Capsaicin (cream, lotion, gel, roll-on, and transdermal patch) is FDA approved for the temporary relief of minor aches and pains associated with backache, strains, and arthritis. It is also approved in patch form by prescription for postherpetic neuralgia and is used for off-label treatment of painful diabetic neuropathy and some forms of pruritus.

Bentoquatam (quaternium-18 bentonite) is a mixture of quaternium-18 (quaternary ammonium chloride salts made from the fatty acids of tallow) and bentonite clay. This organoclay mixture is approved for OTC use as a topical barrier to prevent allergic contact dermatitis to the urushiol resin of poison ivy, oak, or sumac. The 5% topical lotion must be applied prophylactically at least 15 min prior to potential risk for exposure to urushiol and reapplied every 4 h.

Coal tar is a distillation product from coal, a mixture of over 10,000 compounds. It is used in dermatology primarily for the treatment of inflammatory skin conditions such as psoriasis, seborrheic dermatitis, and atopic dermatitis or other forms of eczematous dermatitis. The mechanism of action is unknown although it is known to suppress DNA synthesis. Coal tar has anti-inflammatory, antimicrobial, and antipruritic activity. In addition, it has a photosensitizing effect within the UVA and visible light spectrum between wavelengths of 330 and 550 nm. Multiple formulations and products are available commercially or through compounding, including those containing crude coal tar, coal tar extracts, or coal tar solution (Sandhu and Schwartz, 2011). Coal tar solution, also known as liquor carbonis detergens (LCD), is an alcohol extract of coal tar emulsified with polysorbate 80 to yield a more cosmetically acceptable product. Coal tar may be used in combination with UVB phototherapy (e.g., Goeckerman regimen), topical salicylic acid, or topical corticosteroids. Coal tar products are often poorly tolerated by patients due to its unpleasant odor, messiness, and potential for staining of clothing. It can also cause folliculitis or irritant contact dermatitis. Though occupational exposures to coal tar have been associated with malignancies (e.g., scrotal cancer), patients with psoriasis or atopic dermatitis who are treated with topical coal tar products have not exhibited increased risk of cancer (Menter et al., 2009a).

Anthralin (dithranol), a synthetic version of chrysarobin, is derived from the bark of the Brazilian araroba tree and is used in the treatment of psoriasis and alopecia areata; its mechanisms of action are unclear (Menter et al., 2009a). Use of anthralin has been limited by the potential to cause irritant contact dermatitis and to stain skin, hair, nails, fabrics, and household items.
Brimonidine (0.33% topical gel) is an α1 adrenergic agonist approved for once-daily treatment of persistent erythema of rosacea. It causes temporary vasoconstriction, and rebound erythema has been reported. α1 Adrenergic agonists such as oxymetazoline have been used off label topically for erythematotelangiectatic rosacea as well.

Propranolol and timolol are nonselective β adrenergic antagonists traditionally used for cardiovascular disease. These agents are also effective off label for treatment of infantile hemangiomas requiring intervention (Chen et al., 2013). Topical timolol drops and gel-forming solution are available but do not adequately treat deeper lesions.

Acknowledgment: Eric L. Wyatt, Steven H. Sutter, Lynn A. Drake, Lindy P. Fox, Hans F. Merk, David R. Bickers, and Lowell Goldsmith have contributed to this chapter in earlier editions of this book. We have retained some of their text in the current edition.

### Topical or Intraleosional Cytotoxic, Immunosuppressant, and Immunomodulatory Agents

| 5-Fluouracil | MOA: Actinic keratoses, Superficial basal cell carcinoma, Warts (off label) | See Chapter 66 |
| Bleomycin     | MOA: Genital warts | See Chapter 66 |
| Alkylating agents | MOA: Genital warts | See Chapter 66 |
| Podophyllin resin and podoflinox | MOA: Genital warts | See Chapter 66 |
| Ingenol mebutate | MOA: Genital warts | See Chapter 66 |
| Imiquimod | MOA: Genital warts, Actinic keratoses, Superficial basal cell carcinoma | See Chapter 66 |
| Sinecatechins | MOA: Genital warts | See Chapter 66 |
| mTOR inhibitors | MOA: Off-label use in tuberous sclerosis, complex vascular malformations, and some inflammatory dermatoses | Topical mTOR inhibitors not currently commercially available but may be compounded |
| Topical calcineurin inhibitors | MOA: Off-label use in tuberous sclerosis, complex vascular malformations, and some inflammatory dermatoses | Topical use may decrease potential for side effects seen with systemic use |
| Pimecrolimus | MOA: Genital warts | See Chapter 66 |
| Tacrolimus | MOA: Decreased T-cell activation | See Chapter 66 |

### Targeted Immunotherapies for Psoriasis and Atopic Dermatitis

- **TNF-α inhibitors; IL-12/23 inhibitors; IL-17 inhibitors; PDE4 inhibitors; Jak inhibitors**
  - MOA: Psoriasis
  - Atopic dermatitis: off-label use of PDE4 inhibitors, Jak inhibitors
  - See Chapter 35

### Targeted Antineoplastic Agents

| Smoothened inhibitors Histone deacetylase inhibitors | MOA: Basal cell carcinoma | See Chapter 67 |
| BRAF inhibitors; MEK inhibitors; CTLA4 inhibitors; programmed death 1 inhibitors | MOA: Melanoma | See Chapter 67 |

### Topical Agents for Hyperkeratotic Disorders

| Alpha-hydroxy acids Glycolic acid Lactic acid | MOA: Hyperkeratotic disorders | Potential skin irritation |
| Salicylic acid | MOA: Hyperkeratotic disorders | Potential skin irritation |
| Urea | MOA: Hyperkeratotic disorders | Potential skin irritation |
| Sulfur | MOA: Hyperkeratotic disorders | Potential skin irritation |
| Pungent odor | MOA: possibly through interaction with cysteine, causing reduction to hydrogen sulfide, which may break down keratin | See Chapter 66 |

**Agents Affecting Hair Growth**

| Minoxidil, topical | Androgenetic alopecia | MOA: not fully determined; stimulates and prolongs anagen phase |
| Finasteride, oral | Androgenetic alopecia | MOA: inhibition of 5α-reductase to decrease conversion of testosterone to DHT |
| Dutasteride, oral | Hirsutism (off-label) | Side effects: decreased libido, sexual dysfunction, hypotension |
| Spironolactone, oral | Hirsutism (off-label) | MOA: aldosterone antagonist with antiandrogenic activity |
| | Female pattern alopecia (off-label) | Side effects: breast tenderness, menstrual irregularities, increased urination |
| | | Feminization of male fetus |
| Eflornithine, topical | Unwanted facial hair in women | MOA: ornithine decarboxylase inhibition to decrease hair growth |
| | | Slow hair growth; use in combination with hair removal methods |
| Bimatoprost, topical | Hypotrichosis of the eyelashes | MOA: prostaglandin analogue that increases percentage of hairs in anagen phase |
| | | May cause brown pigmentation of eyelid and iris (permanent) |

Please note that there are numerous additional off-label uses of medications in dermatological conditions. MOA, mechanism of action.

---

### Bibliography

**Suggested Reading**

Humans are exposed to chemicals from their environment daily. Fortunately, mammals have evolved mechanisms to protect themselves from toxic effects of many exogenous chemicals, including the xenobiotic transport and metabolic mechanisms described in Chapters 4–7. While the human body is relatively well adapted to deal with xenobiotics, there are situations in which such environmental agents may cause significant toxicity. The industrial revolution and the development of chemical industries have increased human exposures to chemicals that were previously infrequent or absent. Concern about environmental toxicants has stimulated interest and research in environmental toxicology, the study of how chemicals in our environment adversely affect human health; and in occupational toxicology, the study of how chemicals in the workplace affect human health. Many authoritative textbooks are available in these areas. This chapter does not attempt a thorough coverage; rather, it sets forth a few basic principles, briefly discusses carcinogens and chemoprevention, and then focuses on the pharmacotherapy of heavy metal intoxication.

**Risk Assessment and Management of Environmental Risk**

Environmental exposures to xenobiotics involve large populations exposed to many toxicants at low doses over long periods of time, which poses challenges for assessing the risks from those exposures. Thus, the focus of environmental risk assessment is on the low end of the dose-response curve, using experiments based on chronic exposures. Unlike drugs, which are given to treat a specific disease and should have benefits that outweigh the risks, environmental toxicants are usually only harmful. In addition, exposures to environmental toxicants are involuntary, there is uncertainty about the severity of their effects, and people are much less willing to accept their associated risks.

**Epidemiological Approaches to Risk Assessment**

Epidemiologists use a variety of study designs to look for statistical associations between environmental exposures, including chemical exposures, and health outcomes. This approach has the advantage of examining the effects of real-world exposures to humans but can be expensive and subject to biases and confounding effects.

**Epidemiological Studies**

Several types of epidemiological studies are used to assess risks, each with its own set of strengths and weaknesses.

- **Ecological studies** correlate frequencies of exposures and health outcomes between different geographical regions. These studies are inexpensive and are effective for generating hypotheses but are subject to confounders and are not effective for establishing causality.

- **Cross-sectional studies** examine the prevalence of exposures and outcomes at a single point in time. Such studies are an inexpensive way to determine an association but do not provide a temporal relationship and are not effective for establishing causality. They also can be subject to bias, as a health outcome under study might cause someone to eliminate his or her exposure.

- **Case-control studies** start with a group of individuals affected by a disease; this group then is matched to another group of unaffected individuals for known confounding variables. Questionnaires often are used to evaluate past exposures. This method also is relatively inexpensive and is good for examining rare outcomes because the end point is known. However, case-control studies rely on assessments of past exposures, which can be unreliable and subject to bias.

- **Cohort studies** measure exposures in a large group of people and follow that group for a long time to measure health outcomes. These studies are not as susceptible to bias and are better than case-control studies at establishing causality. However, they are expensive, particularly when measuring rare outcomes, because a large study population is required to observe sufficient disease to obtain statistical significance.

**Treatment for Metal Exposure**

Both is integrated into environmental risk assessment. Risk assessment is used to develop management approaches, such as laws and regulations, to limit exposures to environmental toxicants to a level that is considered safe.
Abbreviations

ARE: antioxidant response element
ATSDR: Agency for Toxic Substances Disease Registry
BAL: British anti-Lewisite (dimercaprol)
BLL: blood lead level
CaNa2EDTA: calcium disodium ethylenediaminetetraacetic acid
CDC: Centers for Disease Control and Prevention
COX-2: cyclooxygenase 2; prostaglandin H synthase II
CV: cardiovascular
DMPS: sodium 2,3-dimercaptopropane sulfonate
EEG: electroencephalogram
EPA: United States Environmental Protection Agency
ER: estrogen receptor
GI: gastrointestinal
GSH: reduced glutathione
GST: glutathione S-transferase
IARC: International Agency for Research on Cancer
IM: intramuscular
IV: intravenous
LOAEL: lowest adverse effect level
MCL: maximum contaminant level
MeHg*: methyl mercury
MMA: monomethylarsonic
NOAEL: no adverse effect level
NOx: nitrogen oxides
NQO1: quinone reductase
NTP: National Toxicology Program
PG: prostaglandin
RID: reference dose
ROS: reactive oxygen species
SC: subcutaneous

Biomarkers

Because of the difficulties in assessing human exposures and the long times required to clinically observe effects on health, epidemiologists often rely on biomarkers in risk assessment. Different types of biomarkers provide different information useful for risk assessment. Biomarkers aim to be specific, only detecting the change in affected individuals, and sensitive, detecting the change in all affected individuals.

- Clinical trials (see Chapter 1) cannot be used to directly measure the effects of environmental toxicants (for obvious ethical reasons) but can be used to examine the effectiveness of an interventional strategy for reducing both exposures and disease.

- Biomarkers of exposure provide information about dose or duration of exposures. Blood and urine concentrations of a chemical or its metabolite measure recent exposures, whereas levels in hair and toenails can measure exposure over a period of months. An example of an unusual exposure biomarker is X-ray fluorescent measurement of bone lead levels, which estimates lifetime exposure to lead.

- Biomarkers of toxicity are used to measure toxic effects at a subclinical level. Examples include measurement of liver enzymes in serum, changes in the quantity or contents of urine, and performance on specialized exams for neurological or cognitive function.

- Biomarkers of susceptibility are used to predict which individuals are likely to develop toxicity in response to a given chemical. Examples include single-nucleotide polymorphisms in genes for metabolizing enzymes involved in the activation or detoxification of a toxicant.

- Some biomarkers simultaneously provide information on exposure, toxicity, or susceptibility. For example, the measurement in the urine of N7-guanine adducts from aflatoxin B1 provides evidence of both exposure and a toxic effect (in this case, DNA damage).

Toxicological Approaches to Risk Assessment

Toxicologists use model systems, including experimental animals, to examine the toxicity of chemicals and predict their effects on humans. Toxicologists typically must test chemicals at higher doses than would be observed in the environment to see enough occurrences of a toxic outcome to obtain statistical significance. As a result, there is often uncertainty about the effects of very low doses of chemicals. To determine the applicability of model systems, toxicologists also study the mechanisms involved in the toxic effects of chemicals, with the goal of predicting whether that mechanism would occur in humans.

To predict the toxic effects of environmental chemicals, toxicologists perform subchronic studies (3 months of treatment for rodents) and chronic studies (2 years for rodents) in at least two different animal models. Doses for these studies are based on shorter preliminary studies, with the goal of having one concentration that does not have a significant effect, one concentration that results in statistically significant toxicity at the low end of the dose-response curve, and one or more concentrations that will have moderate-to-high levels of toxicity. A theoretical dose-response curve for an animal study is shown in Figure 71–1.

An animal study provides two numbers that estimate the risk from a chemical:

- The NOAEL is the highest dose used that does not result in a statistically significant increase in negative health outcomes.
- The LOAEL is the lowest dose that results in a significant increase in toxicity.

The NOAEL is divided by 10 for each source of uncertainty to determine a RfD, which is commonly used as a starting point for determining regulations on human exposures to chemicals. The modifiers used to determine the RfD are based on the uncertainties between experimental and human exposure. The most common modifiers used are for interspecies variability (human to animal) and interindividual variability (human to human), in which case RfD = NOAEL/100. Other modifiers can be used to account for specific experimental uncertainties, such as the unavailability of data from chronic studies. The use of factors of 10 in the denominator for determination of RfD is an application of the “precautionary principle,” which attempts to limit human exposure by assuming a worst-case scenario for each unknown variable.

A major concern with animal studies is that they do not detect effects at low concentrations. Typically, they are designed to obtain statistical significance with a 10%–15% increase in an outcome. As a result, there is considerable uncertainty about what occurs below that level, as demonstrated in Figure 71–1. Toxicologists often assume that there is a threshold dose below which there is no toxicity. However, the shape of the dose-response curve below the NOAEL is not known with certainty and represents a point of departure (POD). The existence of a threshold dose assumes that there are cellular defenses that prevent toxicity at concentrations below a given level, and that they can be overwhelmed. Some carcinogens may not exhibit a threshold, while others for which defense mechanisms exist do and other toxicants with specific molecular targets (e.g., lead) do not exhibit a threshold. Ideally, mechanistic studies should be done to predict which dose-response curve is most likely to fit a given chemical.

Toxicologists perform mechanistic studies to understand how a chemical might cause toxicity. Computer modeling using a compound’s three-dimensional structure to determine quantitative structure-activity relationships (QSAR) is commonly performed on both drugs and environmental chemicals. QSAR approaches can determine which chemicals are likely to exhibit toxicities or bind to specific molecular targets. Cell-based approaches in prokaryotes and eukaryotes are used to determine whether a compound damages DNA or causes cytotoxicity. DNA damage and the resulting mutagenesis often are determined with the Ames test, which uses Salmonella typhimurium strains with specific mutations in the gene needed to synthesize histidine. These strains are treated with chemicals in the presence or absence of a metabolic activating system (usually hepatic xenobiotic metabolizing enzymes). If a compound is a...
mutagen in the Ames test, it reverts the mutation in the histidine operon and allows the bacteria to form colonies on plates with limited histidine. Gene chip microarrays assess gene expression in cells or tissues from animals treated with a toxicant and provide a useful tool to identify the molecular targets and pathways altered by toxicant exposures. The susceptibility of knockout mice to a toxicant can help to determine whether the knocked-out genes are involved in the mechanism of toxicity.

**Carcinogens and Chemoprevention**

**Carcinogenesis**

The IARC classifies the carcinogenicity of compounds into groups based on risk assessments using epidemiologic, human exposure, animal, and mechanistic data. Chemicals in *group 1* are known human carcinogens; *group 2A* are chemicals that are probably carcinogenic in humans; *group 2B* are chemicals that are possibly carcinogenic in humans; *group 3* are chemicals for which data are lacking to suggest a role in carcinogenesis; and *group 4* are those for which the data indicate that they are unlikely to be carcinogens. Table 71–1 provides examples of group 1 carcinogens.

The transformation of a normal cell to a malignancy is a multistage process, and exogenous chemicals can act at one or more of these stages. A classic model of chemical carcinogenesis is *tumor initiation* followed by *tumor promotion*. In this model, an initiator causes gene mutations that increase the ability of cells to proliferate and avoid apoptosis. A promoter does not directly modify genes but changes signaling pathways or the extracellular environment to increase survival, proliferation, or invasiveness of precancerous cells. Although this model is an oversimplification of the many processes of carcinogenesis, it demonstrates the types of changes that must occur for a normal cell to transform into cancer. Chemical carcinogens cause cancer through genotoxic and nongenotoxic mechanisms (Figure 71–2).

**Genotoxic** carcinogens initiate tumor formation through damage to DNA. Typically, genotoxic carcinogens undergo metabolism in a target tissue to a reactive intermediate. This reactive intermediate can directly damage DNA via covalent reaction to form a DNA adduct. Alternatively, it can indirectly damage DNA through the formation of ROS, which can oxidize DNA or form lipid peroxidation products that react with DNA (Mena et al., 2009). If DNA damage from a genotoxic carcinogen is not repaired prior to DNA replication, a mutation can result. If this mutation is in a key tumor suppressor gene or proto-oncogene, it can provide advantages in proliferation or survival. Alternatively, mutations to DNA repair genes can increase the probability that future mutations will occur. With the right extracellular environment, mutations in key genes will allow a cell to proliferate faster than surrounding normal cells and possibly develop into malignant cancer.

Benzo[a]pyrene, a key carcinogen in tobacco smoke, is an example of a genotoxic carcinogen that forms both direct DNA adducts and ROS. Benzo[a]pyrene is oxidized by CYPs to a 7,8-dihydrodiol, which represents a proximate carcinogen (a more carcinogenic metabolite). This metabolite either can undergo a second oxidation step by a CYP to form a diol epoxide, which readily reacts with DNA, or can undergo oxidation by aldo-keto reductases to form a catechol, which will redox cycle to form ROS (Conney, 1982; Penning, 2009).

**Nongenotoxic** carcinogens increase the incidence of cancer without damaging DNA, and most agents in this category are tumor promoters. Many nongenotoxic carcinogens bind to receptors that stimulate proliferation or other tumor-promoting effects, such as tissue invasion and angiogenesis. For example, phorbol esters mimic diacylglycerol and activate PKC isoforms. This in turn stimulates MAPK pathways, leading to proliferation, invasiveness, and angiogenesis (Chapter 3 presents these signaling pathways). In most normal cells, prolonged activation of this pathway stimulates apoptosis, but cells with defective apoptotic mechanisms due to preceding mutation(s) are resistant to this effect. Estrogenic carcinogens activate ERα and stimulate proliferation and invasiveness of estrogen-responsive cells. Chronic inflammation is another mechanism of nongenotoxic carcinogenesis. Inflammatory cytokines stimulate PKC signaling, leading to proliferation, invasiveness, and angiogenesis. Irritants such as asbestos are examples of carcinogens that work through inflammation. Chronic exposure to hepatotoxic chemicals (or chronic liver diseases) also causes nongenotoxic carcinogenesis by stimulating compensatory proliferation to repair the liver damage. This damage and repair process increases the likelihood of DNA damage causing a mutation, causes chronic inflammation, and selects for initiated cells that proliferate faster or are less sensitive to cell death.

Many compounds can also act as complete carcinogens because repeated exposure can cause tumor initiation and promotion. Examples of complete carcinogens include benzo[a]pyrene and ultraviolet radiation. Tumor initiation also may occur through nongenotoxic mechanisms. For example, some heavy metals do not directly react with DNA but interfere with proteins involved in DNA synthesis and repair, increasing the likelihood that an error will be made during replication. Nongenotoxic carcinogens also can cause heritable changes to gene expression by altering the methylation state of cytosines in 5′-CpG-3′ islands of gene promoters. Methylation can silence tumor suppressor genes, while demethylation of proto-oncogenes can increase their expression. These *epigenetic* effects can occur through sustained transcription or silencing of a gene.

Some chemicals enhance the carcinogenesis of other chemicals and thus act as *cocarcinogens*. These chemicals can increase the absorption or change the metabolism of other chemicals, increasing the probability that they form active metabolites in target tissues. They can also interfere with DNA repair, increasing the occurrence of mutations from a second genotoxic carcinogen. For example, ethanol acts as a solvent and increases the absorption of tobacco carcinogens, increasing the risk of head and neck cancers in people who both smoke and drink. Ethanol also depletes GSH, limiting target cells’ ability to detoxify reactive metabolites of carcinogens and ROS.

**Chemoprevention**

Drugs that interfere with the carcinogenic process to prevent cancer before it is diagnosed are termed *chemopreventive agents* (Szabo, 2006;

William et al., 2009). The chemoprevention concept was pioneered during the 1960s by Wattenberg and others, who observed that dietary constituents, such as β-carotene, could prevent cancer in rodents (Wattenberg, 1966). Chemoprevention strategies often are based on epidemiological studies on nutrition, where there are many examples of clear protective effects of plant-based foods and drinks on the incidence of various types of cancer (Fahey and Kensler, 2007). By isolating the active compounds from protective plants, researchers hope to understand their protective mechanisms and develop drugs to prevent cancer. Chemoprevention is an emerging field; a number of compounds for the prevention of cancer are in clinical trials (Table 71–2). Most chemicals tested for chemoprevention have not exhibited a benefit, and in some cases they have increased the risk of cancer (Potter, 2014). There are currently no drugs approved for chemoprevention of environmental carcinogenesis, but there are approved drugs to prevent carcinogenesis due to endogenous estrogen (tamoxifen and raloxifene) and viruses (hepatitis B and human papillomavirus vaccines).

Chemopreventive agents can interfere with initiation or promotion (Figure 71–2). One mechanism of anti-initiation is prevention of carcinogen activation. Isothiocyanates inhibit CYPs involved in activating many carcinogens and also upregulate genes controlled by the antioxidant response element (ARE); the ARE-responsive genes include γ-glutamylcysteine synthase light chain (which catalyzes the rate-determining step in GSH synthesis) and quinone reductase. Increased expression of ARE-regulated genes is predicted to increase the detoxification of proximate carcinogens. Isothiocyanates also stimulate apoptosis of p53-deficient cells via the formation of cytotoxic DNA adducts.

Compounds that act as antioxidants may provide protection because many carcinogens work through the generation of ROS. Some compounds simultaneously prevent carcinogen activation and act as antioxidants.

For example, flavonoids and other polyphenols found in a wide variety of plants are potent antioxidants that also inhibit CYPs and induce expression of ARE-regulated genes. Chlorophyll and other compounds can protect against carcinogens by binding to or reacting with carcinogens or their metabolites and preventing them from reaching their molecular target.

Inflammation is a potential target for chemoprevention through interference with promotion. In phase 3 studies, the COX-2 inhibitor celecoxib demonstrated efficacy at reducing the risk of colorectal cancer. However, this benefit was offset by an increased risk of death due to cardiovascular events, forcing the early termination of the trial (William et al., 2009). Studies examining long-term treatment with aspirin for cardiovascular benefits found that aspirin also reduces the incidence of colorectal adenomas and overall cancer mortality. A phase 3 clinical trial is under way to examine this effect. Naturally occurring compounds such as α-tocopherol have also been hypothesized to exert chemoprevention by reducing inflammation. However, α-tocopherol actually increased the risk of prostate cancer in a phase 3 trial (Potter, 2014).

Another approach to chemoprevention is disruption of nuclear receptor signaling. Retinoids reduce the incidence of head and neck cancers, and is one of the first successful uses of chemoprevention in humans (Evans and Kaye, 1999; William et al., 2009). Retinoids are also effective for the treatment for acute promyelocytic leukemia (see Section VII). However, in large clinical trials, retinoids increased the incidence of lung cancer, particularly amongst women, and had other unacceptable toxicities (Ommen et al., 1996).

The selective ER modulators tamoxifen and raloxifene reduced the incidence of breast cancer in high-risk women in large phase 3 clinical trials and are approved for chemoprevention in these patients (Vogel et al., 2006). The success of selective ER modulators for chemoprevention provides a proof-of-principle that the development of compounds based on mechanistic predictions of antipromotion activity can lead to effective drugs for the prevention of cancer.

**Aflatoxin B1**

Agents are being developed as chemopreventive agents of hepatocarcinogenesis mediated by aflatoxin B1. Aflatoxins are produced in regions with hot and wet climates by *Aspergillus flavus*, a fungus that is a common contaminant of foods, especially corn, peanuts, cottonseed, and tree nuts. As a result of exposure to aflatoxin, human hepatocellular carcinoma is a serious problem in subtropical and tropical regions of Latin America, Africa, and Southeast Asia. Human exposure to aflatoxin in the U.S. is rare and not thought to have a significant impact on health (IARC, 2002).

**ADME**

Aflatoxin B1 is readily absorbed from the GI tract and initially distributed to the liver, where it undergoes extensive first-pass metabolism (Guengerich et al., 1996). Aflatoxin B1 is metabolized by CYPs 1A2 and 3A4 to yield either an 8,9-epoxide or products hydroxylated at the 9 position (aflatoxin M1) or 3 position (aflatoxin Q2; Figure 71–3). While the hydroxylation products are detoxification products, the 8,9-epoxide reacts with DNA and is responsible for aflatoxin carcinogenesis. The 8,9-epoxide is short lived and undergoes detoxification via nonenzymatic hydrolysis or conjugation with GSH. Aflatoxin M1 enters the circulation and is excreted in urine and milk.

**Toxicity**

Aflatoxin B1 primarily targets the liver, although it also is toxic to the GI tract and hematological system. High-dose exposures result in acute necrosis of the liver, leading to jaundice and, in many cases, death. Acute toxicity from aflatoxin is rare in humans and requires consumption of milligram quantities of aflatoxin per day for multiple weeks. Chronic exposure to aflatoxins results in cirrhosis of the liver and immunosuppression.

**Carcinogenicity**

Based on increased incidence of hepatocellular carcinoma in humans exposed to aflatoxin and on supporting animal and mechanistic data,
IARC has classified aflatoxin B as a known human carcinogen (group 1) (IARC, 2002). Aflatoxin exposure and the hepatitis B virus work synergistically to cause hepatocellular carcinoma. Aflatoxin or hepatitis B exposure alone increases the risk of hepatocellular carcinoma 3.4- or 7.3-fold, respectively; those exposed to both have a 59-fold increased risk of cancer compared to unexposed individuals (Groopman et al., 2005).

Aflatoxin primarily forms DNA adducts at deoxyguanosine residues, reacting at either the N1 or N7 position (IARC, 2002); the 8,9-epoxide of aflatoxin B, readily reacts with amines. The N7-guanine adduct mispairs with adenine, leading to G → T transversions. Human aflatoxin exposure is associated with hepatocellular carcinomas bearing an AGG-to-AGT mutation in codon 249 of the p53 tumor suppressor gene, resulting in the replacement of an arginine with cysteine (Hussain et al., 2007).

Several mechanisms for the synergistic interaction between hepatitis B and aflatoxin are under investigation (Sylla et al., 1999). The X gene of the hepatitis B virus encodes a protein, HBx, that binds to and inhibits p53, resulting in suppressed nucleotide excision repair of aflatoxin B, adducts (Hussain et al., 2007). Hepatitis B also alters the metabolism of aflatoxin B, by upregulating CYP genes, including CYP3A4, and decreases GSH S-transferase activity. In addition, hepatocellular proliferation to repair damage done by hepatitis B infection increases the likelihood that aflatoxin-induced DNA adducts will cause mutations. The hepatotoxic and tumor-promoting effects of hepatitis B also could provide a more favorable environment for the proliferation and invasion of initiated cells.

**Chemoprevention of Aflatoxin-Induced Hepatocellular Carcinoma**

The relationship between aflatoxin metabolism and its carcinogenicity makes it an appealing target for chemopreventive strategies that modify its metabolism (Figure 71–3). Inhibiting CYP activity or increasing GSH conjugation will reduce the intracellular concentration of the 8,9-epoxide and prevent DNA adduct formation (Groopman et al., 2008; Kessler et al., 2004). Oltipraz, an antischistosomal drug, potently inhibits CYPs and induces genes regulated by the ARE that are involved in GSH synthesis. Oltipraz increases the excretion of the N-acetylcysteine aflatoxin conjugate, indicating enhanced GSH conjugation of the epoxide. At 500 mg/week, oltipraz reduced the levels of aflatoxin M, consistent with inhibition of CYP activity.

Green tea polyphenols (GTPs) also have been used to modify aflatoxin metabolism in exposed human populations. Individuals receiving a daily dose of 500 or 1000 mg (equivalent to 1 or 2 L of green tea) demonstrated a small decline in the formation of aflatoxin-albumin adducts and a large increase in the excretion of the N-acetylcysteine aflatoxin conjugate, consistent with a protective effect.

Another approach used for the chemoprevention of aflatoxin hepatic carcinogenesis is the use of “interceptor molecules.” Chlorophyllin, a mixture of water-soluble chlorophyll salts, binds tightly to aflatoxin in the GI tract, forming a complex that is not absorbed. In vitro, chlorophyllin inhibits CYP activity and acts as an antioxidant. In a phase 2 trial, administration of 100 mg of chlorophyllin with each meal reduced aflatoxin–N7-guanine adduct levels in the urine. Because of the strong interaction between hepatitis B and aflatoxin in carcinogenesis, the hepatitis B vaccine reduces the sensitivity of people to the induction of cancer by aflatoxin. Primary prevention of aflatoxin exposure through hand or fluorescent sorting of crops to remove those with fungal contamination also reduces human exposure. A cost-effective primary prevention approach is to improve food storage to limit the spread of *Aspergillus flavus*, which requires a warm and humid environment.

**Water and Air Pollution**

The U.S. EPA protects the public from water and airborne pollutants by enforcing compliance with the Clean Water Act (protects the public and the environment from water pollution); the Safe Drinking Water Act (ensures the quality of the drinking water); and the Clean Air Act (to protect the public from air pollutants). Under these laws, the EPA combines scientific risk assessment with economic analyses and other factors to develop regulations on the release or presence of specific pollutants to limit their effect on human health and the environment.

Toxicity screening of many water contaminants has led to the development of maximum contaminant levels (MCLs) for drinking water. To protect against potential adverse health effects, a primary MCL sets a level for a contaminant that must not be exceeded. The primary MCL is based on consideration of the toxic dose-response curve and on whether a sufficiently sensitive analytical method exists to measure the contaminant for compliance purposes. A secondary MCL is not enforced but is established for aesthetic value (e.g., taste, color, odor) that may not affect health. Currently, there is concern about pharmaceutical waste in the water supply, but MCLs have not been set for these compounds.

The EPA also monitors six priority air pollutants (CO, Pb, NOx, O3, particulate matter, and SO2) that they have determined play the largest role in human health effects from air pollution. The EPA sets National Ambient Air Quality Standards in which local levels of these pollutants may not be exceeded within a given time frame. Measurements made by stationary
Metals are an important class of environmental toxicants; they are ubiquitous environmental contaminants that come from both natural and anthropogenic sources. The CDC lists arsenic, mercury, and lead as the top three pollutants of concern, based on their toxicity and levels of human exposure. Although the toxicity of high levels of exposure to metals has long been known, the effects of low-dose chronic exposure to metals have only recently been appreciated. Many of the toxic metals in the environment also are carcinogens (Table 71–3). In addition, several essential metals also are toxic under conditions of overdose. Copper and iron are associated with toxicities, primarily targeting the liver through generation of ROS.

Lead

Chronic exposure to very low levels of lead has major deleterious effects, particularly for children.

Exposure

Despite substantial improvements over the past four decades, lead exposure remains a major concern, especially for children. In the U.S., paint containing lead for use in and around households was banned in 1978, while the use of tetraethyl lead in gasoline was phased out between 1976 and 1996. Despite these bans, past use of lead carbonate and lead oxide in paint and tetraethyl lead in gasoline remain the primary sources of lead exposure. Lead is not degradable and remains in dust, soil, and the paint of older homes. Young children are exposed to lead by nibbling sweet-tasting paint chips or ingesting dust and soil in and around older homes. Renovation or demolition of older buildings may cause substantial lead exposure. Removal of lead from gasoline reduced lead levels in air by more than 90% between 1982 and 2002, but lead fallout from air pollution remains in soils, particularly in urban environments. Lead was also commonly used in plumbing and can leach into drinking water. Lead exposure also has been traced to other sources, such as inhalation of dusts and fumes at firing ranges, retained bullets, artists’ paint pigments, ashes and fumes from painted wood, lead-glazed pottery, lead toys, non-Western folk medicines, cosmetics, jewelers’ wastes, home battery manufacture, and lead type (ATSDR, 2007b). BLLs in children have steadily decreased since the 1970s, when the mean level was 15 μg/dL. Currently, the average BLL in children is at 1.3 μg/dL.

The CDC recently updated its recommendations to reflect the modern understanding that there is no safe level of lead exposure for children (CDC, 2012). The CDC no longer provides a “level of concern,” as any lead exposure to a child is concerning. Instead, the CDC emphasizes primary prevention of lead exposure in all children and recommends that children with a BLL that places them in the top 2.5% (currently ≥ 5 μg/dL) be identified as in need of exposure reduction and additional screening. They did not change the existing recommendation that physicians consider chelation therapy for children with a BLL above 45 μg/dL.

Occupational exposure to lead also has decreased because of protective regulations. Occupational exposure generally is through inhalation of lead-containing dust and lead fumes. Workers in lead smelters and storage battery factories are at the greatest risk for lead exposure. Other workers at risk for lead exposure are those associated with steel welding or cutting, construction, rubber and plastic industries, printing, firing ranges, radiator repair shops, and any industry where lead is flame soldered (ATSDR, 2007b).

Chemistry and Mode of Action

Lead exists in its metallic form and as divalent or tetravalent cations. Divalent lead is the primary environmental form; inorganic tetravalent lead compounds are not found naturally. Organo-lead complexes primarily occur with tetravalent lead and include the gasoline additive tetraethyl lead.

Lead toxicity results from molecular mimicry of other divalent metals (Garza et al., 2006), principally zinc and calcium. Because of its size and electron affinity, lead alters protein structure and can inappropriately activate or inhibit protein function.

ADME

Lead exposure occurs through ingestion or inhalation. GI absorption of lead varies considerably with age and diet. Children absorb a much higher percentage of ingested lead (~40% on average) than adults (~<20%). Absorption of ingested lead is drastically increased by fasting. Dietary calcium or iron deficiencies increase lead absorption, suggesting that lead is absorbed through divalent metal transporters. The absorption of inhaled lead (~90%) generally is much more efficient than through dietary intake. Tetravalent lead is readily absorbed through the skin, but transdermal absorption does not occur with inorganic lead.

About 99% of lead in the bloodstream binds to hemoglobin. Lead initially distributes in the soft tissues, particularly in the tubular epithelium of the kidney and the liver. Over time, lead is redistributed and deposited in bone, teeth, and hair. About 95% of the adult body burden of lead is

bCERCLA, Comprehensive Environmental Response, Compensation, and Liability Act.
found in bone. Growing bones will accumulate higher levels of lead and can form lead lines visible by radiography. Bone lead is slowly reabsorbed into the bloodstream, which can be accelerated when calcium levels are depleted, including during pregnancy. Small quantities of lead accumulate in the brain, mostly in gray matter and the basal ganglia. Lead readily crosses the placenta.

Lead is excreted primarily in the urine. The concentration of lead in urine is directly proportional to its free concentration in plasma (~1% of the total BLL). Lead is excreted in milk and sweat and deposited in hair and nails. The serum half-life of lead is 1–2 months, with a steady state achieved in about 6 months. Lead accumulates in bone, where its half-life is estimated at 20–30 years.

**Health Effects**

Although the effects of high-dose lead poisoning have been known for more than 2000 years, the insidious toxicities of chronic low-dose lead poisoning (BLL < 20 μg/dL) have only recently been discovered. Lead is a nonspecific toxicant; the most sensitive systems are the nervous, hematological, cardiovascular, and renal systems (Table 71–4). Uncovering the effects of low-level lead exposure on complex health outcomes, such as neurobehavioral function and blood pressure, has been the subject of extensive research and the object of considerable public concern.

**Neurotoxic Effects.** The biggest concerns with low-level lead exposure are cognitive delays and behavior changes in children (ATSDR, 2007b; Bellinger and Bellinger, 2006). The developing nervous system is very sensitive to the toxic effects of lead, with effects persisting down to the lowest measurable levels of lead (Cranfield et al., 2003; Lanphear et al., 2005).

Lead neurotoxicity primarily results from inhibition of Ca++ transporters and channels and altered activities of Ca++ responsive proteins, including PKC and calmodulin (Bellinger and Bellinger, 2006; Garza et al., 2006). These actions limit the normal activation of neurons in response to Ca++ release and cause inappropriate production or release of neurotransmitters. Lead affects multiple neurotransmitter pathways, including the dopaminergic, cholinergic, and glutaminergic systems. At high concentrations, lead causes disruption of membranes, including the blood-brain barrier, increasing their permeability to ions.

Lead alters brain development by interfering with the pruning of synapses, neuronal migration, and the interactions between neurons and glial cells. Neurotransmitter release and PKC signaling determine which synapses are maintained and which are lost during brain development; this process is disrupted by lead. Lead-induced alterations in brain development can result in decreased IQ, poor performance on exams, language and motor deficits, and behavioral problems such as distractibility, impulsivity, aggression, short attention span, and inability to follow simple sequences of instructions (ATSDR, 2007b; CDC, 2014). There is no evidence for a threshold; associations are evident even at the lowest measurable BLL (Figure 71–4). The cognitive and behavioral changes caused by lead vary considerably among children and may depend on the timing of exposure.

Children with very high BLL (>70 μg/dL) are at risk for encephalopathy. Symptoms of lead-induced encephalopathy include lethargy, vomiting, irritability, anorexia, and vertigo, which can progress to ataxia, delirium, and eventually coma and death. Mortality rates for lead-induced encephalopathy are about 25%, and most survivors develop long-term sequelae such as seizures and severe cognitive deficits.

Adults can also develop encephalopathy from lead exposure, although they are less sensitive than children. Workers chronically exposed to lead can develop neuromuscular deficits, termed lead palsy. Symptoms of lead palsy, including wrist drop and foot drop, were commonly associated with painters and other lead-exposed workers during previous eras but are rare today. Lead induces degeneration of motor neurons, usually without affecting sensory neurons. Studies in older adults have shown associations between lead exposure and decreased performance on cognitive function tests, suggesting that lead accelerates neurodegeneration due to aging (ATSDR, 2007b).

**Figure 71–4**  Effect of childhood lead exposure on IQ. Childhood exposure to lead shows a nonlinear dose-response relationship, with a steeper curve at low concentrations of lead (estimated dose-response curve based on data from Lanphear et al., 2005, and Canfield et al., 2003). For comparison, the average BLL from three iterations of the National Health and Nutritional Examination Survey are shown (Wheeler and Brown, 2013).
**Cardiovascular and Renal Effects.** Elevated blood pressure is a lasting effect of low-level lead exposure (BLL < 10 μg/dL). Adults who were exposed to lead during infancy and childhood have elevated blood pressure even in the absence of a recent exposure (ATSDR, 2007b). Lead exposure is associated with an increased risk of death due to cardiovascular and cerebrovascular disease (Schober et al., 2006).

In the kidney, low-level lead exposure (BLL < 10 μg/dL) depresses glomerular filtration. Higher levels (>30 μg/dL) cause proteinuria and impaired transport, while very high levels (>50 μg/dL) cause permanent physical damage, including proximal tubular nephropathy and glomerulosclerosis. Impaired glomerular filtration and elevated blood pressure are closely interrelated and likely have causative effects on one another (ATSDR, 2007b).

The cardiovascular effects of lead are thought to involve the production of ROS, which react with NO to prevent vasodilation (Vaziri and Khan, 2007). It is not known how lead reduces glomerular filtration rate, although there is evidence that lead targets kidney mitochondria and interferes with the electron transport chain (ATSDR, 2007b).

**Other Effects.** Lead causes both immunosuppression and increased inflammation, primarily through changes in helper T-cell and macrophage signaling; these effects can occur at low BLLs in children (Dietert and Piepenbrink, 2006). Lead inhibits the activity of several enzymes involved in the biosynthesis of heme; this effect persists down to very low BLL (<10 μg/dL; Figure 71–5). Chronic high-dose lead intoxication is associated with hypochromic microcytic anemia, which is observed more frequently in children and is morphologically similar to iron-deficient anemia. Acute high-dose lead exposure affects the smooth muscle of the gut, producing intestinal symptoms, termed lead colic.

**Carcinogenesis.** The IARC classifies lead in group 2A, “probably carcinogenic to humans” (IARC, 2006). Epidemiological studies show associations between lead exposure and cancers of the lung, brain, kidney, and stomach. Rodents exposed to lead develop kidney tumors, and some associations between lead exposure and cancers of the lung, brain, kidney, and stomach. Rodents exposed to lead develop kidney tumors, and some rats develop gliomas. Lead is not mutagenic but increases clastogenic events. Lead carcinogenesis may result from inhibition of DNA-binding zinc-finger proteins, including those involved in DNA repair and synthesis. Lead is a good example of a nongenotoxic carcinogen.

**Mercury**

- **Exposure**
  - Inorganic mercury cations and metallic mercury are found in the Earth's crust, and mercury vapor is released naturally into the environment through volcanic activity and off-gassing from soils. Mercury also enters the atmosphere through human activities, such as combustion of fossil fuels and gold mining. In 2011, the EPA set the first standards to reduce mercury emissions from coal-fired power plants. Once in the air, metallic mercury is photo-oxidized to inorganic mercury, which can then be deposited in aquatic environments in rain. Microorganisms can then conjugate inorganic mercury to form methyl mercury. Methyl mercury concentrates in muscle and other tissues and will bioaccumulate up the food chain (Figure 71–6). As a result, mercury concentrations in aquatic organisms at the top of the food chain, such as swordfish or sharks, are high (ATSDR, 1999).

  - The primary source of exposure to Hg^+ in the general population is vaporization of Hg^0 in dental amalgam. Human exposure to organic mercury primarily is through the consumption of fish. Other foods contain inorganic mercury at low levels (ATSDR, 1999).

  - Workers are exposed to Hg^0 and inorganic mercury, most commonly through exposure to vapors. The highest risk for exposure is in the chloralkali industry (i.e., bleach) and in other chemical processes in which mercury is used as a catalyst. Mercury is a component of many devices, including alkaline batteries, fluorescent bulbs, thermometers, and scientific equipment, and exposure occurs during the production of these devices. Dentists also are exposed to Hg^0 from amalgam. Hg^0 can be used to extract gold during mining, which results in substantial occupational exposure. Mercuric salts are used as pigments in paints (ATSDR, 1999).

  - *Thimerosal* is an antimicrobial agent used as a preservative in some vaccines. Its use is controversial because it releases ethyl mercury, which is chemically similar to methyl mercury. Some parents have expressed concern that thimerosal might contribute to autism. Even though these concerns were based on a long-discredited report, the American Academy of Pediatrics and the U.S. Public Health Service issued a call for thimerosal's replacement in vaccines to improve the prevalence of vaccination, and thimerosal was removed from childhood vaccines in 2001 (Ball et al., 2001). Concurrently, studies found no association between thimerosal use in vaccines and negative outcomes, and thimerosal is still used...

**Chemistry and Mode of Action**

There are three general forms of mercury of concern to human health. Metallic, or elemental, mercury (Hg\(_0\)) is the liquid metal found in scientific equipment and dental amalgam; it is volatile, and exposure is often to the vapor. Inorganic mercury can be either monovalent (mercurous, Hg\(_{1+}\)) or divalent (mercuric, Hg\(_{2+}\)) and forms a variety of salts. Organic mercury compounds consist of divalent mercury complexed with one or two alkyl groups. Methyl mercury (MeHg\(^+\)), which is formed environmentally from inorganic mercury by aquatic microorganisms, is of most concern. Both Hg\(_{2+}\) and MeHg\(^+\) readily form covalent bonds with sulfur, which causes most of the biological effects of mercury. At very low concentrations, mercury reacts with sulphydryl residues on many proteins and disrupts their functions. Microtubules are particularly sensitive to the toxic effects of mercury, which disrupts their formation and can catalyze their disassembly (Clarkson, 2002). There also may be an autoimmune component to mercury toxicity.

**ADME**

The vapor of Hg\(_0\) is readily absorbed through the lungs (~70%–80%), but GI absorption of Hg\(_0\) is negligible. Once absorbed, Hg\(_0\) distributes throughout the body and crosses membranes, such as the blood-brain barrier and the placenta, via diffusion. Hg\(_0\) is oxidized by catalase in cells to form Hg\(_{2+}\). Shortly after exposure, some Hg\(_{2+}\) is eliminated in exhaled air. After a few hours, distribution and elimination of Hg\(_0\) resemble the properties of Hg\(_{2+}\). Hg\(_0\) vapor can be oxidized to Hg\(_{2+}\) in the brain and retained (ATSDR, 1999).

Gastrointestinal absorption of mercury salts varies depending on the individual and on the particular salt and averages about 10%–15%. Hg\(_{1+}\) will form Hg\(_0\) or Hg\(_2^+\) in the presence of sulphydryl groups. Hg\(_{2+}\) is primarily excreted in the urine and feces; a small amount also can be reduced to Hg\(_0\) and exhaled. With acute exposure, the fecal pathway predominates, but following chronic exposure, urinary excretion becomes more important. All forms of mercury also are excreted in sweat and breast milk and deposited in hair and nails. The t\(_{1/2}\) for inorganic mercury is approximately 1–2 months (ATSDR, 1999).

Complexes between MeHg\(^+\) and cysteine resemble methionine and can be recognized by transporters for that amino acid and taken across membranes (Ballatori, 2002). Orally ingested MeHg\(^+\) is almost completely absorbed from the GI tract. MeHg\(^+\) readily crosses the blood-brain barrier and the placenta and distributes fairly evenly to the tissues, although concentrations are highest in the kidneys (ATSDR, 1999). MeHg\(^+\) can be demethylated to form inorganic Hg\(_{2+}\). The liver and kidney exhibit the highest rates of demethylation, but this also occurs in the brain. MeHg\(^+\) is excreted in the urine and feces, with the fecal pathway dominating. The t\(_{1/2}\) for MeHg\(^+\) is about 2 months. The toxicodynamic properties of MeHg\(^+\) are thought to result from molecular mimicry.

**Health Effects**

**Metallic Mercury.** Inhalation of high levels of Hg\(_0\) vapor over a short duration is acutely toxic to the lung. Respiratory symptoms of Hg\(_0\) exposure start with cough and tightness in the chest and can progress to interstitial pneumonitis and severely compromised respiratory function. Other initial symptoms include weakness, chills, metallic taste, nausea, vomiting, diarrhea, and dyspnea. Acute exposure to high doses of Hg\(_0\) is also toxic to the CNS, with symptoms similar to those of chronic exposure (Figure 71–7).

Toxicity to the nervous system is the primary concern with chronic exposure to Hg\(_0\). Symptoms include tremors (particularly of the hands); emotional lability (irritability, shyness, loss of confidence, and nervousness); insomnia; memory loss; muscular atrophy; weakness; paresthesia; and cognitive deficits. These symptoms intensify and become irreversible with increases in duration and concentration of exposure. Other common symptoms of chronic mercury exposure include kidney damage, tachycardia, labile pulse, severe salivation, and gingivitis.

**Inorganic Salts of Mercury.** Ingestion of Hg\(_{2+}\) salts is intensely irritating to the GI tract, leading to vomiting, diarrhea, and abdominal pain. Acute exposure to Hg\(_{1+}\) or Hg\(_{2+}\) salts (typically in suicide attempts) leads to renal tubular necrosis, resulting in decreased urine output and often acute renal failure. Chronic exposures also target the kidney, with glomerular injury predominating.

**Organic Mercury.** The CNS is the primary target of MeHg\(^+\) toxicity. Symptoms of high-dose MeHg\(^+\) exposure include visual disturbances, ataxia, paresthesia, fatigue, hearing loss, slurring of speech, cognitive deficits, muscle tremor, movement disorders, and, following severe exposure, paralysis and death. The developing nervous system exhibits increased sensitivity to MeHg\(^+\). Children exposed in utero can develop severe symptoms, including mental retardation and neuromuscular deficits, even in
The absence of symptoms in the mother. In adults, MeHg1+ causes lesions in specific areas of the brain, while the brains of children exposed in utero sustain widespread damage (Clarkson, 2002). The effects of low-dose MeHg1+ exposure from routine consumption of fish are difficult to assess due to the opposing beneficial effects of ω-3 fatty acids found in fish oils, and studies have produced discrepant results (Grandjean et al., 1999; Myers et al., 2003).

**Treatment**
Termination of exposure to Hg0 is critical, and respiratory support may be required. Emesis may be used within 30–60 min of exposure to Hg1+ or Hg2+, provided the patient is awake and alert and there is no corrosive injury. Maintenance of electrolyte balance and fluids is important for these patients. Chelation therapy is beneficial in patients with acute inorganic or metallic mercury exposure. There are limited treatment options for MeHg1+. Chelation therapy does not provide clinical benefits, but nonabsorbable thiol resins may be beneficial by preventing absorption of MeHg1+ from the GI tract. Because of the conflicting effects of mercury and ω-3 fatty acids, there is considerable controversy regarding the restriction of fish intake in women of reproductive age and children. The EPA recommends limiting fish intake to 12 oz (two meals) per week. Many experts feel this recommendation is too conservative. The recommendation that women consume fish that is lower in mercury content (i.e., canned light tuna, salmon, pollock, catfish) and avoid top predators, such as swordfish, shark, and tilapia, is not controversial.

**Arsenic**
Arsenic is a metalloid that is common in rocks and soil. Arsenic compounds have been used for more than 2400 years as both therapeutic agents and poisons. In the late 19th century, Robert Ehrlich coined the term magic bullet to describe his work using the organic arsenical compound arsphenamine for the treatment for syphilis. The use of arsenic in drugs has been mostly phased out, but arsenic trioxide is still used as an effective chemotherapy agent for acute promyelocytic leukemia (see Chapter 68).

**Exposure**
The primary source of exposure to arsenic is through drinking water. Arsenic naturally leaches out of soil and rocks into well and spring water (Mead, 2005). Levels of arsenic in drinking water average 2 μg/L (ppb) in the U.S. but can be more than 50 μg/L (five times the MCL set by the EPA) in private well water. Drinking water from other parts of the world, particularly Taiwan, China, Argentina, Chile, Bangladesh, and eastern India, sometimes is contaminated with much higher levels of arsenic (sometimes several hundred micrograms per liter), and widespread poisonings have resulted (see Figure 71–8). Arsenic can enter the environment through human activities, such as the use of arsenic-containing pesticides, mining, and burning of coal. Food, particularly seafood, often is contaminated with arsenic. Arsenic in seafood exists primarily as organic compounds (i.e., arsobetaine), which are much less toxic than inorganic arsenic. The average daily human intake of arsenic is 10 μg/d, almost exclusively from food and water.

Before 2003, more than 90% of arsenic used in the U.S. was as a preservative in pressure-treated wood, but the lumber industry has voluntarily replaced arsenic with other preservatives. Arsenic-treated wood is thought to be safe unless burned. The major source of occupational exposure to arsenic is in the production and use of organic arsenicals as herbicides and insecticides. Exposure to metallic arsenic, arsenic, arsenic trioxide, and gallium arsenide also occurs in high-tech industries, such as the manufacture of computer chips and semiconductors.

**Chemistry and Mode of Action**
Arsenic exists in its elemental form and trivalent (arsenites/arsenious acid) and pentavalent (arsenates/arsenic acid) states. Arsenic (AsH3) is a gaseous hydride of trivalent arsenic that exhibits toxicities that are distinct from other forms. Organic compounds of either valence state of arsenic are formed in animals. The toxicity of a given arsenical is related to the rate of its clearance from the body and its ability to concentrate in tissues. In general, toxicity increases in the sequence: organic arsenicals < As3+ < As5+ < AsH3.

Like mercury, trivalent arsenic compounds form covalent bonds with sulphydryl groups. The pyruvate dehydrogenase (PDH) complex is particularly sensitive to inhibition by trivalent arsenicals: The two sulphydryl groups of lipoic acid that participate in acetate transfer to coenzyme A react with arsenic to form a six-membered ring, effectively inhibiting PDH and other lipoamide-containing enzymes. Inorganic arsenic (pentavalent) inhibits the electron transport chain. It is thought that arsenate competitively substitutes for phosphate during the formation of ATP, forming an unstable arsenate ester that is rapidly hydrolyzed.

**ADME**
The absorption of arsenic compounds is directly related to their aqueous solubility. Poorly water-soluble compounds such as arsenic sulfide, lead
arsenate, and arsenic trioxide are not well absorbed. Water-soluble arsenic compounds are readily absorbed via inhalation and ingestion. GI absorption of arsenic dissolved in drinking water is more than 90% (ATSDR, 2007a). At low doses, arsenic is fairly evenly distributed throughout the tissues of the body. Nails and hair, due to their high sulphydryl content, exhibit high concentrations of arsenic. After an acute high dose (i.e., fatal poisoning), arsenic is preferentially deposited in the liver and, to a lesser extent, kidney, with elevated levels also observed in the muscle, heart, spleen, pancreas, lungs, and cerebellum. Arsenic readily crosses the placenta and blood-brain barrier.

Arsenic undergoes biotransformation in humans and animals (Figure 71–9). Trivalent compounds can be oxidized back to pentavalent
compounds, but there is no evidence for demethylation of methylated arsenicals. Humans excrete much higher levels of MMA compounds than most other animals (ATSDR, 2007a). Because the pentavalent methylated arsenic compounds have greatly reduced toxicity, the methylation pathway was long thought to be a detoxification pathway. However, the trivalent methylated arsenicals actually are more toxic than inorganic arsenite due to an increased affinity for sulfhydryl groups, and formation of MMA\textsuperscript{IV} now is considered a bioactivation pathway (Aposhian and Aposhian, 2006).

Elimination of arsenicals by humans primarily is in the urine, although some is also excreted in feces, sweat, hair, nails, skin, and exhaled air. Compared to most other toxic metals, arsenic is excreted quickly, with a \( t_{1/2} \) of 1–3 days. In humans, ingested inorganic arsenic that appears in urine is of toxicities and has been associated with effects on every organ system tested (ATSDR, 2007a). Humans also are exposed to large organic arsenic compounds in fish, which are relatively nontoxic. Humans are the most sensitive species to the toxic effects of inorganic arsenic. Acute exposure to large doses of arsenic (>70–180 mg) often is fatal. Death immediately following arsenic poisoning typically is the result of its effects on the heart and GI tract. Death sometimes occurs later as a result of arsenic’s combined effect on multiple organs.

**Health Effects**

With the exception of arsine gas, the various forms of inorganic arsenic exhibit similar toxic effects. Inorganic arsenic exhibits a broad range of toxicities and has been associated with effects on every organ system tested (ATSDR, 2007a). Humans also are exposed to large organic arsenic compounds in fish, which are relatively nontoxic. Humans are the most sensitive species to the toxic effects of inorganic arsenic. Acute exposure to large doses of arsenic (>70–180 mg) often is fatal. Death immediately following arsenic poisoning typically is the result of its effects on the heart and GI tract. Death sometimes occurs later as a result of arsenic’s combined effect on multiple organs.

**Cardiovascular System.** Acute and chronic arsenic exposure cause myocardial depolarization, cardiac arrhythmias, and ischemic heart disease; these are known side effects of arsenic trioxide for the treatment for leukemia. Chronic exposure to arsenic can cause peripheral vascular disease, the most dramatic example of which is “blackfoot disease,” a condition characterized by cyanosis of the extremities, particularly the feet, progressing to gangrene. Blackfoot disease is endemic in regions of Taiwan and the United States where arsenic levels in drinking water are high. Arsenic exposure can cause peripheral vascular disease following chronic exposure.

**Skin.** Dermal symptoms often are diagnostic of arsenic exposure. Arsenic induces hyperkeratinization of the skin (including formation of multiple corns or warts), particularly of the palms of the hands and the soles of the feet. It also causes areas of hyperpigmentation interspersed with spots of hypopigmentation. These symptoms can be observed in individuals exposed to drinking water with arsenic concentrations of at least 100 \( \mu g \)/L and are typical in those chronically exposed to much higher levels. Hyperpigmentation can be observed after 6 months of exposure; hyperkeratinization takes years. Children are more likely to develop these effects than adults (ATSDR, 2007a; Mead, 2003).

**Gastrointestinal Tract.** Acute or subacute ingestion of high-dose arsenic is associated with GI symptoms ranging from mild cramping, diarrhea, and vomiting to GI hemorrhaging and death. GI symptoms are caused by increased capillary permeability, leading to fluid loss. At higher doses, fluid forms vesicles that can burst, leading to inflammation and necrosis of the submucosa and then rupture of the intestinal wall. GI symptoms are not observed with chronic exposure to lower levels of arsenic.

**Nervous System.** The most common neurological effect of acute or subacute arsenic exposure is peripheral neuropathy involving both sensory and motor neurons. This effect is characterized by the loss of sensation in the hands and feet, often followed by muscle weakness. Neuropathy occurs several days after exposure and can be reversible following cessation of exposure, although recovery usually is not complete. Arsenic exposure may cause intellectual deficits in children (Wasserman et al., 2007). Arsenic may also inhibit heme synthesis. In the liver, arsenic causes fatty infiltrations, central necrosis, and cirrhosis of varying severity. The action of arsenic on renal capillaries, tubules, and glomeruli can cause severe kidney damage. Inhaled arsenic is irritating to the lungs, and inhaled arsenic may induce bronchiitis progressing to bronchopneumonia in some individuals. Chronic exposure to arsenic is associated with an increased risk of diabetes.

**Carcinogenesis.** Regions with very high arsenic levels in drinking water consistently have substantially higher rates of skin cancer, bladder cancer, and lung cancer. There also are associations between arsenic exposure and other cancers, including liver, kidney, and prostate tumors. Inhalation exposure to arsenic in occupational settings causes lung cancer. IARC classifies arsenic as “carcinogenic to humans (Group 1).” The developing fetus and young children may be at increased risk of arsenic carcinogenesis because humans exposed to arsenic in utero and in early childhood have a greatly elevated risk of lung cancer (Smith et al., 2006). Studies in rodents also have observed increased cancer risks from in utero exposure and suggest that the second trimester of pregnancy represents a critical susceptibility window (Waalke et al., 2007).

Arsenic does not directly damage DNA; rather, arsenic is thought to work through changes in gene expression, DNA methylation, inhibition of DNA repair, generation of oxidative stress, or altered signal transduction pathways (Hartwig et al., 2002; Saliukow and Zhikovitch, 2008). Arsenic compounds can act as tumor promoters or cocarcinogens in rodents, particularly when combined with ultraviolet light. In humans, exposure to arsenic potentiates lung tumorigenesis from tobacco smoke. Smokers in regions with high concentrations of arsenic in the drinking water have a 5-fold increased risk of cancer over smokers living in low-arsenic regions (Ferreccio et al., 2000). Arsenic also has endocrine-disrupting activities on several nuclear steroid hormone receptors, enhancing hormone-dependent transcription at very low concentrations and inhibiting it at slightly higher levels.

**Arsine Gas.** Arsine gas, formed by reduction of arsenic in an industrial setting, is a rare cause of poisonings. Arsine induces rapid and often-fatal hemolysis, which probably results from arsine combining with hemoglobin and reacting with \( O_2 \). A few hours after exposure, patients can develop headache, anorexia, vomiting, asthenia, abdominal pain, chills, hemoglobinuria, bilirubinemia, and anuria. Jaundice appears after 24 h. Arsine induces renal toxicities that can progress to kidney failure. Approximately 25% of cases of arsine exposure result in death.

**Treatment**

Following acute exposure to all forms of arsenic, the patient should be stabilized and further absorption of the poison should be prevented.
Close monitoring of fluid levels is important because arsenic can cause fatal hypovolemic shock. Chelation therapy is effective following short-term exposure to arsenic but has little or no benefit in chronically exposed individuals. Exchange transfusion to restore blood cells and remove arsenic is often warranted following arsenic gas exposure (Ibrahim et al., 2006).

### Cadmium

Cadmium was discovered in 1817 and first used industrially in the mid-20th century. Cadmium is resistant to corrosion and exhibits useful electrochemical properties, which has led to its use in electroplating, galvanization, plastics, paint pigments, and nickel-cadmium batteries.

### Exposure

In the general population, the primary source of exposure to cadmium is through food, with an estimated average daily intake of 50 μg. Cadmium also is found in tobacco and tobacco smoke; a cigarette contains 1–2 μg of cadmium (Jarup and Akeson, 2009). Workers in smelters and other metal-processing industries can be exposed to high levels of cadmium, particularly by inhalation.

### Chemistry and Mode of Action

Cadmium exists as a divalent cation and does not undergo oxidation-reduction reactions. There are no covalent organometallic complexes of cadmium of toxicological significance. The mechanism of cadmium toxicity is not fully understood. Like lead and other divalent metals, cadmium can replace zinc in zinc-finger domains of proteins and disrupt them. Through an unknown mechanism, cadmium induces formation of ROS, resulting in lipid peroxidation and GSH depletion. Cadmium also upregulates inflammatory cytokines and may disrupt the beneficial effects of NO.

### ADME

Cadmium is not well absorbed from the GI tract (1.5%–5%) but is absorbed via inhalation (~10%). Cadmium primarily distributes first to the liver and later to the kidney, which together account for 50% of the absorbed dose. Cadmium distributes fairly evenly to other tissues but does not cross the blood-brain barrier or the placenta. Cadmium primarily is excreted in the urine and exhibits a t\(_{1/2}\) of 10–30 years (ATSDR, 2012b).

### Health Effects

#### Toxicity

Acute cadmium toxicity is due to local irritation along the absorption route. Inhaled cadmium causes respiratory tract irritation with severe, early pneumonitis accompanied by chest pains, nausea, dizziness, and diarrhea. Toxicity may progress to fatal pulmonary edema. Ingested cadmium induces nausea, vomiting, salivation, diarrhea, and abdominal cramps; the vomitus and diarrhea often are bloody. Symptoms of chronic cadmium toxicity vary by exposure route. The lung is an important target of inhaled cadmium, while the kidney is a major target of cadmium from both inhalation and ingestion. Cadmium bound to metallothionein is transported to the kidney, where it can be released. Renal toxicity results from increased excretion of low-molecular-weight proteins, especially β\(_2\) microglobulin and retinol-binding protein. Cadmium also causes glomerular injury, with a resulting decrease in filtration. Chronic occupational exposure to cadmium is associated with an increased risk of renal failure and death. There is no evidence for a threshold level for cadmium's effects on the kidney; cadmium levels consistent with normal dietary exposure can cause renal toxicity.

#### Carcinogenicity

Chronic occupational exposure to inhaled cadmium increases the risk of developing lung cancer (IARC, 1993; NTP, 2004). The mechanism of cadmium carcinogenesis is not fully understood. Cadmium causes chromosomal aberrations in exposed workers and treated animals and human cells. It also increases mutations and impairs DNA repair in human cells (NTP, 2004). Cadmium substitutes for zinc in DNA repair proteins and polymerases and may inhibit nucleotide excision repair, base excision repair, and the DNA polymerase responsible for repairing single-strand breaks (Hartwig et al., 2002). There is evidence that cadmium also alters cell signaling pathways and disrupts cellular controls of proliferation (Waisberg et al., 2003). Thus, cadmium acts as a nongenotoxic carcinogen.

#### Treatment

Treatment for cadmium poisoning is symptomatic. Patients who have inhaled cadmium may require respiratory support. Patients with kidney failure as a result of cadmium poisoning may require a transplant. There is no evidence for clinical benefit from chelation therapy following cadmium poisoning, and chelation therapy may result in adverse effects (ATSDR, 2012b).

### Chromium

Chromium is an industrially important metal used in a number of alloys, particularly stainless steel, which contains at least 11% chromium. Chromium can be oxidized to multiple valence states, with trivalent (Cr\(^{3+}\)) and hexavalent (Cr\(^{6+}\)) being the two forms of biological importance. Chromium exists almost exclusively as the trivalent form in nature, and Cr\(^{6+}\) is an essential metal involved in the regulation of glucose metabolism. Cr\(^{3+}\) is thought to be responsible for the toxic effects of chromium (ATSDR, 2012a).

#### Exposure

Exposure to chromium in the general population primarily is through the ingestion of food, although there also is exposure from drinking water and air. Workers are exposed to chromium during chromate production, stainless steel production and welding, chromium plating, ferrochrome alloy and chrome pigment production, and in tanning industries. Exposure usually is to a mixture of Cr\(^{3+}\) and Cr\(^{6+}\).

#### Chemistry and Mode of Action

Chromium occurs in its metallic state or in any valence state between trivalent and hexavalent. Cr\(^{3+}\) is the most stable and common form. Cr\(^{6+}\) is corrosive and is readily reduced to lower valence states. The primary reason for the different toxicological properties of Cr\(^{6+}\) and Cr\(^{3+}\) is thought to be differences in their absorption and distribution. Hexavalent chromate resembles sulfate and phosphate and can be taken across membranes by anion transporters. Once inside the cell, Cr\(^{3+}\) undergoes a series of reduction steps, ultimately forming Cr\(^{6+}\), which is thought to cause most of the toxic effects. Trivalent chromium readily forms covalent interactions with DNA. Hexavalent chromium also induces oxidative stress and hypersensitivity reactions.

#### ADME

Absorption of inhaled chromium depends on its solubility, valence state, and particle size. Smaller particles are deposited deeper in the lungs. Absorption into the bloodstream of hexavalent and soluble forms is higher than the trivalent or insoluble forms, with the remainder often retained in the lungs. Approximately 50%–85% of inhaled Cr\(^{6+}\) particles (<5 μm) are absorbed. Absorption of ingested chromium is less than 10% and varies depending on water solubility. Cr\(^{3+}\) crosses membranes by facilitated transport, while Cr\(^{6+}\) crosses by diffusion. Cr\(^{6+}\) is distributed to all of the tissues and crosses the placenta. The highest levels are attained in the liver, kidney, and bone; Cr\(^{3+}\) is also retained in erythrocytes. Excretion primarily is through urine, with small amounts also excreted in bile and breast milk and deposited in hair and nails. The t\(_{1/2}\) of ingested Cr\(^{6+}\) is about 40 h; the t\(_{1/2}\) of Cr\(^{3+}\) is about 10 h (ATSDR, 2012a).

### Health Effects

#### Toxicity

Acute exposure to very high doses of chromium causes death via damage to multiple organs, particularly the kidney. Chronic low-dose exposure to chromium can result in respiratory irritation, dermatitis, and immune system sensitization.
Chromium exposure causes toxicity at the site of contact. Workers exposed to inhaled chromium develop symptoms of lung and upper respiratory tract irritation, decreased pulmonary function, and pneumonia. Chronic exposure to chromium via ingestion, including after mucociliary clearance of inhaled particles, causes symptoms of GI irritation (oral ulcer, diarrhea, abdominal pain, indigestion, and vomiting). CrVI is a dermal irritant and can cause ulceration or burns. Low-dose exposure by any route causes some individuals to become sensitized. These individuals will develop allergic dermatitis following dermal exposure to chromium, including products containing metallic chromium. Chromium-sensitized workers often also develop asthma following inhalation exposure (ATSDR, 2012a).

Carcinogenicity. The CrVIII compounds are group 1 known human carcinogens (IARC, 1990). There is insufficient evidence for carcinogenicity from metallic and trivalent chromium (classified in IARC group 3). Workers exposed to CrVIII via inhalation have elevated incidence of and mortality from lung and nasal cancer. Environmental exposure to CrVIII in drinking water increases the risk of developing stomach cancer.

There are multiple potential mechanisms for chromium carcinogenicity (Salnikow and Zhitkovich, 2008). Reduction of CrVIII to CrVI occurs with concomitant oxidation of cellular molecules. Ascorbate is the primary reductant, but other molecules, including GSH, lipids, proteins, and DNA, also can be oxidized. CrVI forms a large number of covalent DNA adducts, primarily at the phosphate diester backbone. The DNA adducts are not very mutagenic and are repaired by nucleotide excision repair. It is thought that the high level of nucleotide excision repair activity following chromium exposure contributes to carcinogenesis, either by preventing repair of mutagenic lesions formed by other carcinogens or through the formation of single-strand breaks due to incomplete repair. Chromium also forms cross-links between DNA and protein. Chronic inflammation due to chromium-induced irritation also may promote tumor formation.

Treatment

There are no standard protocols for treatment for acute chromium poisoning. One approach that has shown promise in rodents is the use of reductants such as ascorbate, GSH, or N-acetylcysteine to reduce CrVIII to CrVI after exposure but before absorption to limit bioavailability (ATSDR, 2012a). These compounds and EDTA also increase urinary excretion of chromium after high-dose exposure, particularly if given soon enough to prevent uptake into cells. Exchange transfusion to remove chromium from plasma and erythrocytes may be beneficial.

Treatment for Metal Exposure

The most important response to environmental or occupational exposures to metals is to eliminate the source of the exposure. It also is important to stabilize the patient and provide symptomatic treatment.

Treatment for acute metal intoxications often involves the use of chelators. A chelator is a compound that forms stable complexes with metals, typically as five- or six-membered rings. Formation of complexes between chelators and metals should prevent or reverse metal binding to biological ligands. The ideal chelator should be highly soluble in water, be resistant to biotransformation, reach sites of metal storage, form stable and nontoxic complexes with toxic metals, and be readily excreted as a metal-chelator complex. A low affinity for the essential metals calcium and zinc also is desirable because toxic metals often compete with these metals for protein binding.

In cases of acute exposure to high doses of most metals, chelation therapy reduces toxicity. However, following chronic exposure, chelation therapy does not show clinical benefits beyond those of cessation of exposure alone and, in some cases, does more harm than good. Chelation therapy may increase the neurotoxic effects of heavy metals and is only recommended for acute poisonings. The structures of the most commonly used chelators are shown in Figure 71–10.

Ethylenediaminetetraacetic Acid

EDTA and its various salts are effective chelators of divalent and trivalent metals. CaNa₂EDTA is the preferred EDTA salt for metal poisoning, provided that the metal has a higher affinity for EDTA than calcium. CaNa₂EDTA is effective for the treatment for acute lead poisoning, particularly in combination with dimercaprol, but is not an effective chelator of mercury or arsenic in vivo.

Chemistry and Mode of Action

The pharmacological effects of CaNa₂EDTA result from chelation of divalent and trivalent metals in the body. Accessible metal ions with a higher affinity for CaNa₂EDTA than Ca²⁺ will be chelated, mobilized, and usually excreted. Because EDTA is charged at physiological pH, it does not significantly penetrate cells. CaNa₂EDTA mobilizes several endogenous metallic cations, including zinc, manganese, and iron. Additional supplementation with zinc following chelation therapy may be beneficial. The most common therapeutic use of CaNa₂EDTA is for acute lead intoxication. CaNa₂EDTA does not provide clinical benefits for the treatment for chronic lead poisoning. CaNa₂EDTA is available as edetate calcium disodium (Calcium Disodium Versenate). Intramuscular administration of CaNa₂EDTA results in good absorption, but pain occurs at the injection site; consequently, the chelator injection often is mixed with a local anesthetic or administered intravenously. For intravenous use, CaNa₂EDTA is diluted in either 5% dextrose or 0.9% saline and is administered slowly by intravenous drip. A dilute solution is necessary to avoid thrombophlebitis.

ADME

Less than 5% of CaNa₂EDTA is absorbed from the GI tract. After intramuscular administration, CaNa₂EDTA has a t½ of 20–60 min. In blood, CaNa₂EDTA is found only in the plasma. CaNa₂EDTA is excreted in the urine by glomerular filtration, so adequate renal function is necessary for successful therapy. Altering either the pH or the rate of urine flow has no effect on the rate of excretion. There is very little metabolic degradation of EDTA. The drug is distributed mainly in the extracellular fluids; little gains access to the spinal fluid (5% of the plasma concentration).

Toxicity

The principal toxic effect of CaNa₂EDTA is on the kidney. Repeated large doses of the drug can eventually cause degeneration of proximal tubular cells. The early renal effects usually are reversible, and urinary abnormalities disappear rapidly with cessation of treatment. The most likely mechanism of toxicity is chelation of essential metals, particularly zinc, in proximal tubular cells. To minimize nephrotoxicity, adequate urine
production should be established prior to and during treatment with CaNa₂EDTA. For patients with lead encephalopathy and cerebral edema, CaNa₂EDTA can lead to a potentially fatal increase in intracranial pressure following intravenous administration. Intramuscular administration is preferred for these patients. Rapid intravenous administration of a form lacking calcium, such as Na₂EDTA, causes hypocalcemic tetany. However, a slow infusion (<15 mg/min) administered to a normal individual elicits no symptoms of hypocalcemia because the change in the concentration of Ca²⁺ in the plasma and total body is negligible. Other side effects associated with CaNa₂EDTA include malaise, fatigue, and excessive thirst, followed by the sudden appearance of chills and fever and subsequent myalgia, frontal headache, anorexia, occasional nausea and vomiting, and rarely, increased urinary frequency and urgency. CaNa₂EDTA is teratogenic in laboratory animals, probably as a result of zinc depletion; it should be used in pregnant women only under conditions in which the benefits clearly outweigh the risks (Kalia and Flora, 2005). Other possible effects include sneezing, nasal congestion, and lacrimation; glycosuria; anemia; dermatitis with lesions strikingly similar to those of vitamin B₆ deficiency; transitory lowering of systolic and diastolic blood pressures; prolonged prothrombin time; and T-wave inversion on the electrocardiogram.

**Dimercaprol**

Dimercaprol was developed during World War II as an antidote to lewisite, a vesicant arsenical war gas, hence its alternative name, British anti-Lewisite (BAL). Arsenicals and other heavy metals form a stable and relatively nontoxic chelate ring with dimercaprol.

**Chemistry and Mode of Action**

The pharmacological actions of dimercaprol result from formation of chelation complexes between its sulfhydryl groups and metals. Dissociation of dimercaprol-metal complexes and oxidation of dimercaprol occur in vivo. The sulfur-metal bond may be labile in the acidic tubular urine, which may increase the delivery of metal to renal tissue and increase toxicity. The dosage regimen should maintain a concentration of dimercaprol in plasma adequate to favor the continuous formation of the more stable 2:1 (BAL-metal) complex. However, because of pronounced and dose-related side effects, excessive plasma concentrations must be avoided. The concentration in plasma therefore must be maintained by repeated dosage until the metal is excreted. Dimercaprol is most beneficial when given very soon after exposure to the metal because it is more effective in preventing inhibition of sulfhydryl enzymes than in reactivating them. Dimercaprol limits toxicity from arsenic, gold, and mercury, which form mercaptides with essential cellular sulfhydryl groups. It also is used in combination with CaNa₂EDTA to treat lead poisoning. Dimercaprol should not be used in iron, cadmium, or selenium poisoning because the resulting metal complexes are more toxic than the metal alone, especially to the kidneys.

**ADME**

Dimercaprol is given by deep intramuscular injection as a 100-mg/mL solution in peanut oil and should not be used in patients who are allergic to peanuts. Peak dimercaprol concentrations in blood are attained in 30–60 min. The t½ is short, and metabolic degradation and excretion essentially are complete within 4 h. Dimercaprol and its chelates are excreted in both urine and bile. Dimercaprol is contraindicated for use following chronic exposures to heavy metals because it does not prevent neurotoxic effects. There is evidence in laboratory animals that dimercaprol mobilizes lead and mercury from various tissues to the brain (Andersen and Aaseth, 2002). This effect may be due to the lipophilic nature of dimercaprol and is not observed with its more hydrophilic analogues described further in the chapter (see Succimer and Sodium 2,3-Dimercaptopropane-1-sulfonate).

**Toxicity**

Side effects occur in about 50% of subjects receiving 5 mg/kg intramuscularly. Dimercaprol causes a rise in systolic and diastolic arterial pressures, accompanied by tachycardia. The pressure rises immediately but returns to normal within 2 h. Dimercaprol also can cause anxiety and unrest, nausea and vomiting, headache, a burning sensation in the mouth and throat, a feeling of constriction or pain in the throat and chest, conjunctivitis, blepharospasm, lacrimation, rhinorrhea, salivation, tingling of the hands, a burning sensation in the penis, sweating, abdominal pain, and the occasional appearance of painful sterile abscesses at the injection site. The dimercaprol-metal complex breaks down easily in an acidic medium; production of alkaline urine protects the kidney during therapy. Children react similarly to adults, although about 30% also may experience a fever that disappears on drug withdrawal. Dimercaprol is contraindicated in patients with hepatic insufficiency, except when this condition is a result of arsenic poisoning.

**Succimer**

Succimer (2,3-dimercaptosuccinic acid [DMSA]) has been approved in the U.S. for treatment of children with BLL greater than 45 μg/dL. Because of its oral availability, improved toxicity profile, and selective chelation of heavy metals, succimer also is used off label for the treatment of adults with lead poisoning and for the treatment for arsenic and mercury intoxication, although no large clinical trials have been undertaken for these indications.

**Chemistry and Mode of Action**

Succimer is an orally effective chelator that is chemically similar to dimercaprol but contains two carboxylic acids that modify the spectrum of absorption, distribution, and chelation of the drug. It has an improved toxicity profile over dimercaprol.

**ADME**

After absorption, succimer is biotransformed to a mixed disulfide with cysteine (Aposhian and Aposhian, 2006). Succimer lowers BLL and attenuates lead toxicity. The succimer–lead chelate is eliminated in both urine and bile. The fraction eliminated in bile can undergo enterohepatic circulation.

Succimer has several desirable features over other chelators. It is orally bioavailable, and because of its hydrophilic nature, it does not mobilize metals to the brain or enter cells. It also does not significantly chelate essential metals such as zinc, copper, or iron. As a result of these properties, succimer exhibits a much better toxicity profile relative to other chelators. Animal studies suggest that succimer also is effective as a chelator of arsenic, cadmium, mercury, and other toxic metals (Andersen and Aaseth, 2002; Kalia and Flora, 2005).

**Toxicity**

Succimer is much less toxic than dimercaprol. The most commonly reported adverse effects are nausea, vomiting, diarrhea, and loss of appetite. In a few patients, rash necessitates discontinuation of therapy. Transient elevations in hepatic transaminases have been observed with succimer treatment.

**Sodium 2,3-Dimercaptopropane-1-sulfonate**

Another dimercaprol compound, DMPS, is used for the chelation of heavy metals. DMPS is not approved by the FDA but is approved for use in Germany. DMPS is available from compounding pharmacies and is used by some doctors in the U.S.

**Chemistry and Mode of Action**

DMPS is a clinically effective chelator of lead, arsenic, and especially mercury. It is orally available and is rapidly excreted, primarily through the kidneys. It is negatively charged and exhibits distribution properties similar to those of succimer. DMPS is less toxic than dimercaprol but mobilizes zinc and copper and thus is more toxic than succimer. In a small clinical trial, DMPS exhibited some clinical benefit for the treatment for chronic arsenic poisoning (Kalia and Flora, 2005), but more thorough clinical studies are needed.

**Penicillamine; Trientine**

Penicillamine is an effective chelator of copper, mercury, zinc, and lead and promotes the excretion of these metals in the urine. Penicillamine
is indicated for use in patients with Wilson disease (excess body burden of copper due to diminished excretion) and is used in other heavy metal intoxications. Penicillamine is more toxic and is less potent and selective for chelation of heavy metals relative to other available chelation drugs. It is therefore not a first-line treatment for acute intoxication with lead, mercury, or arsenic. However, because it is inexpensive and orally bioavailable, it often is given at fairly low doses following treatment with CaNa₂EDTA or dimercaprol to ensure that the concentration of metal in the blood stays low following the patient’s release from the hospital.

**ADME**

Penicillamine is well absorbed (40%–70%) from the GI tract. Food, antacids, and iron reduce its absorption. Peak concentrations in blood are obtained 1–3 h after administration. Penicillamine is relatively stable in vivo compared to its unmethylated parent compound cysteine. Hepatic biotransformation is required for degradation of penicillamine; very little drug is excreted unchanged. Metabolites are found in both urine and feces. N-Acetylpenicillamine is more effective than penicillamine in protecting against the toxic effects of mercury, presumably because it is more resistant to metabolism.

**Therapeutic Use**

Penicillamine is available for oral administration. For chelation therapy, the usual adult dose is 1–1.5 g/d in four divided doses, given on an empty stomach to avoid interference by metals in food. Penicillamine is used in Wilson disease, cystinuria, and rheumatoid arthritis (rarely). For the treatment for Wilson’s disease, 1–2 g/d usually is administered in four divided doses. The urinary excretion of copper should be monitored to determine whether the dosage of penicillamine is adequate.

**Toxicity**

Penicillamine induces cutaneous lesions, including urticaria, macular or papular reactions, pemphigoid lesions, lupus erythematosus, and dermatomyositis. It also causes dryness and scaling. Cross-reactivity with penicillin may be responsible for some episodes of urticarial or maculopapular reactions with generalized edema, pruritus, and fever that occur in as many as one-third of patients taking penicillamine. Hematological reactions may be fatal and include leukopenia, aplastic anemia, and agranulocytosis. Renal toxicity induced by penicillamine usually is manifested as reversible proteinuria and hematuria, but it may progress to nephrotic syndrome with membranous glomerulopathy. Rare fatalities have been reported from Goodpasture syndrome. Severe dyspnea, although uncommon, has been reported from penicillamine-induced bronchial asthma. Myasthenia gravis also has been induced by long-term therapy with penicillamine. A specific schedule for physical and laboratory monitoring for skin, blood, kidney, lung, liver, and other toxicities is published in the manufacturer’s product labeling.

Penicillamine is a teratogen in laboratory animals, but for pregnant women with Wilson disease, the benefits outweigh the risks. Less serious side effects include nausea, vomiting, diarrhea, dyspepsia, anorexia, and a transient loss of taste for sweet and salt, which is relieved by supplementation of the diet with copper. Contraindications to penicillamine therapy include pregnancy in the absence of Wilson disease, renal insufficiency, or a previous history of penicillamine-induced agranulocytosis or aplastic anemia. Penicillamine increases the requirement for pyridoxine; supplementation with 25 mg daily is advised.

**Trientine**

Trientine (triethylenetetramine dihydrochloride) is an acceptable alternative for patients with Wilson disease who are intolerant of penicillamine. Trientine is effective orally. Maximal daily doses of 2 g for adults or 1.5 g for children are taken in two to four divided portions on an empty stomach. Iron deficiency may occur during trientine therapy; this can be overcome with short courses of iron therapy, but iron and trientine should not be ingested within 2 h of each other.

**Deferoxamine; Deferasirox; Deferiprone**

**Chemistry and Mode of Action**

Deferoxamine is isolated as the iron chelate from Streptomyces pilosus and is treated chemically to obtain the metal-free ligand. Deferoxamine (defereroxamine mesylate, desferal) has a remarkably high affinity for ferric iron ($K_a = 10^{31} M^{-1}$) coupled with a very low affinity for calcium ($K_a = 10^{3} M^{-1}$). In vitro, it removes iron from hemosiderin and ferritin and, to a lesser extent, from transferrin. Iron in hemoglobin or cytochromes is not removed by deferoxamine.

**ADME and Therapeutic Use**

Deferoxamine is poorly absorbed after oral administration, and parenteral (intravenous, intramuscular, or subcutaneous) administration is required. For acute iron toxicity, intramuscular administration is preferred, except for patients in cardiovascular collapse or shock. For patients in shock, the drug is administered intravenously at 10–15 mg/kg/h by constant infusion for the first 1000 mg. If additional treatment is needed beyond 1000 mg, it should be administered at a rate not to exceed 125 mg/h. Faster rates of infusion usually are associated with hypotension. For acute iron poisoning without cardiovascular collapse or shock, defereroxamine should be given intramuscularly at a dose of 50 mg/kg with a maximum dose of 1 g. Subsequent doses of 500 mg may be given, if needed, every 4–12 h. Hypotension also can occur with the intramuscular route. For chronic iron intoxication (e.g., thalassemia), subcutaneous administration is recommended. Continuous subcutaneous administration should be given to achieve a dose of 1–2 g/d. The duration of the infusion (8–24 h) should be individualized to the patient. Poorly compliant patients with thalassemia may be given defereroxamine by slow intravenous infusion (rate not to exceed 15 mg/kg/h) prior to or after receiving transfusion. Deferoxamine may also be administered via an intramuscular dose of 0.5–1.0 g/d. Deferoxamine is not recommended in primary hemochromatosis; phlebotomy is the treatment of choice. Off label, deferoxamine has also been used for the chelation of aluminum in dialysis patients.

Deferoxamine is metabolized to unknown products by plasma enzymes. The parent drug and its metabolites are readily excreted in the urine.

**Toxicity**

Deferoxamine can cause a number of allergic reactions, including pruritus, wheals, rash, and anaphylaxis. Other adverse effects include dysuria, abdominal discomfort, diarrhea, fever, leg cramps, and tachycardia. Occasionally, cases of cataract formation have been reported. Deferoxamine may cause neurotoxicity during long-term, high-dose therapy for transfusion-dependent thalassemia major; both visual and auditory changes have been described. A “pulmonary syndrome” has been associated with high-dose (10–25 mg/kg/h) deferoxamine therapy; tachyphilia, hypoxia, fever, and eosinophilia are prominent symptoms. Contraindications to the use of deferoxamine include renal insufficiency and anuria; during pregnancy, the drug should be used only if clearly indicated.

**Deferasirox; Deferiprone**

Deferasirox and deferiprone are oral chelators that are FDA approved to treat chronic iron overload in patients receiving transfusions. Deferasirox is also indicated for the treatment for chronic iron overload in nontransfusion-dependent thalassemia syndromes. Because of their oral availability, these drugs may allow for better compliance rates for patients with thalassemia. Both drugs form an uncharged chelate with iron and appear to be more effective than deferoxamine at reducing cardiac iron. However, both carry black-box warnings (deferasirox for renal failure, hepatic failure, GI hemorrhage; deferiprone for agranulocytosis, neutropenia), and there are currently insufficient data to recommend replacing deferoxamine as the first-line treatment for chronic iron overload.

**Acknowledgment**

Curtis D. Klaassen contributed to this chapter in earlier editions of this book. We have retained some of his text in the current edition.

THE PRESCRIPTION AS A COMMODITY

Latin Not Spoken Here

In writing prescriptions, use English (in the U.S.) or the dominant language of the patient. Latin is no longer the international language of medicine, but a number of commonly used abbreviations derive from obsolete Latin usage and persist in prescription writing. Avoid using them. Non-utuntur Latin.

Some Latin seems firmly embedded in pharmacy practice. “Rx” is said to be an abbreviation for the Latin word recipere, meaning “take” or “take thus,” as a direction to a pharmacist, preceding the physician’s “recipe” for preparing a medication. The abbreviation “Sig” for the Latin Signatura, is used on the prescription to mark the directions for administration of the medication.

Who Can Prescribe Medicines?

Prescription writing in the U.S. is regulated by state boards of pharmacy. In many states, healthcare practitioners other than MD and DO physicians can write prescriptions, although in some cases narcotics are excluded. Licensed dentists, podiatrists, PAs, nurse practitioners, pharmacists, and clinical psychologists can prescribe medications under various circumstances.

Current Practice

The prescription consists of the superscription, the inscription, the subscription, the siga, and the name and signature of the prescriber, all contained on a single form (Figure AI–1). The superscription includes the date the prescription order is written; the name, address, weight, and age of the patient; and the Rx (Take). The body of the prescription, or inscription, contains the name and amount or strength of the drug to be dispensed or the name and strength of each ingredient to be compounded.

The subscription is the instruction to the pharmacist, usually consisting of a short sentence, such as “dispense 30 tablets.” The siga or “Sig” is the instruction for the patient regarding how to take the prescription, interpreted and transposed onto the prescription label by the pharmacist. In the U.S., prescriptions should always be written in English. Many physicians continue to use Latin abbreviations, such as, “1 cap tid pc.” This will be interpreted by the pharmacist as “take one capsule three times daily after meals.” However, the use of Latin abbreviations for these directions only mystifies the prescription and is discouraged. The pharmacist should always write the label in English (or, as appropriate, in the language of the patient). The use of such abbreviations or symbols is a confounding practice; many serious dispensing errors can be traced to the use of abbreviations.

Avoid the instruction “take as directed.” Such directions assume an understanding on the part of the patient that may not be realized and are inadequate for the pharmacist, who must determine the intent of the physician before dispensing the medication. Including directions provides an additional measure of safety for the patient because the pharmacist can confirm the correct medication is being dispensed for the prescribed regimen. The best directions to the patient will include a reminder of the intended purpose of the medication by including such phrases as “for relief of pain” or “to relieve itching.” The correct route of administration is reinforced by the choice of the first word of the directions. For an oral dosage form, the directions should begin with take or give; for externally applied products, the word apply; for suppositories, insert; and for eye, ear, or nose drops, place is preferable to “instill.”

Include Patient Information and Dosage Calculations

The patient’s name and address are needed on the prescription order to ensure that the correct medication goes to the proper patient and also for identification and recordkeeping. For medications whose dosage involves a calculation, a patient’s pertinent factors, such as weight, age, or body surface area, also should be listed on the prescription; both the calculated dose and the dosage formula used, such as “240 mg every 8 h (40 mg/kg/d),” should be included to allow another healthcare professional to double check the prescribed dosage. Pharmacists always should recalculate dosage equations when filling such prescriptions. Medication orders in hospitals and some clinic settings, such as those for antibiotics or anti-seizure medications that are sometimes difficult to adequately dose (e.g., phenytoin), can specify the patient diagnosis and desired drug and request dosing by the clinical pharmacist. This is commonly done for drugs with significant adverse effect potential, such as vancomycin.

Proper Use of Prescription Pad

Prescription pad blanks are normally imprinted with a heading that gives the name of the physician and the address and phone number of the practice site (Figure AI–1). When using institutional blanks that do not bear
Abbreviations

USP/NF: USP/National Formulary

Figure AI–1  The prescription. The prescription must be accurately and legibly prepared to identify the patient, the medication to be dispensed, and the mode of drug administration. Avoid abbreviations and Latin; they lead to dispensing errors. Include the therapeutic purpose in the subscription (e.g., “for control of blood pressure”) to prevent errors in dispensing. For example, the use of losartan for the treatment of hypertension may require 100 mg/d (1.4 mg/kg/d), whereas for treatment of congestive heart failure, the dose of this angiotensin II receptor antagonist generally should not exceed 50 mg/d. Including the therapeutic purpose of the prescription also can assist patients in organizing and understanding their medications. Including the patient’s weight on the prescription can be useful in avoiding dosing errors, particularly when drugs are administered to children.
that will influence their prescribing habits; use of the original medical literature and online resources such as the Cochrane evidentiary reviews (http://www.cochrane.org) will instruct the prescriber's best judgment. The amount of a drug to be dispensed should be clearly stated and should be only that needed by the patient. Excessive amounts should never be dispensed because this not only is expensive for the patient but also may lead to accumulation of medicines, which can lead to harm to the patient or members of the patient’s family if used inappropriately. Better to require several refills of a prescription than to prescribe and dispense more than necessary at one time.

**Controlled Substances**

In the U.S., the DEA within the Department of Justice is responsible for the enforcement of the federal CSA. The DEA regulates each step of the handling of controlled substances from manufacture to dispensing (21 U.S.C. § 811). The law provides a system that is intended to prevent diversion of controlled substances from legitimate uses. Substances that come under the jurisdiction of the CSA are divided into five schedules (Box AI–1); individual states may have additional schedules. Physicians must be authorized to prescribe controlled substances by the board of pharmacy in the jurisdiction in which they are licensed, and they must be registered with the DEA or exempted from registration as defined under the CSA. The number on the certificate of registration must be indicated on all prescription orders for controlled substances. Criminal prosecution and penalties for misuse generally depend on the schedule of a substance and the amount of drug in question.

**Prescribing Controlled Substances**

To be valid, a prescription for a controlled substance must be issued for a legitimate medical purpose by an individual practitioner acting in the usual course of his or her professional practice. An order that does not meet these criteria is not considered a legitimate prescription within the meaning of the law and thus does not protect either the physician who issues it or the pharmacist who dispenses it. Most states prohibit physicians from prescribing controlled substances for themselves. It is prudent to follow this guideline even if compliance is not mandated by law.

Specific requirements, both state and federal, apply to prescriptions for schedule II drugs. For example, all such prescriptions must be written in ink, and refills of schedule II drugs are not allowed. Whether intended for schedule II or lesser scheduled medications, prescriptions for controlled substances must, by law, include the patient’s full name and address and the practitioner’s full name, address, and DEA registration number. The prescription must also include the drug name, strength, quantity, directions for use, and the number of refills, if allowed (based on the category of the drug). The CSA requires that all orders for controlled substances be dated as of, and signed on, the day issued and prohibits filling or refilling orders for substances in schedules III and IV beyond more than 6 months after their date of issuance. State agencies may impose additional regulations, such as requiring that prescriptions for controlled substances be printed on triplicate or state-issued prescription pads or restricting the use of a particular class of drugs for specific indications. All medical personnel should be familiar with the latest CDC recommendations for prescribing opioids for chronic pain (Table 20–7).

**Oral Orders**

Prescriptions for schedule III, IV, and V medications may be telephoned to a pharmacy by a physician in the same manner as a prescription for a noncontrolled substance, although it is in the physician’s best interest to keep his or her DEA number as private as possible (see Preventing Diverion). Schedule II prescriptions may be telephoned to a pharmacy only in emergency situations, that is:

- Immediate administration is necessary.
- No appropriate alternative treatment is available.
- It is not reasonably possible for the physician to provide a written prescription prior to the dispensing.

For an emergency prescription, the quantity must be limited to the amount adequate to treat the patient during the emergency period, and the physician must have a written prescription delivered to the pharmacy for that emergency within 72 h. If mailed, the prescription must be postmarked within 72 h. The pharmacist must notify the DEA if this prescription is not received.

**Refills**

No prescription order for a schedule II drug may be refilled under any circumstance (CFR Title 21 §1306). Pre-dated original prescriptions may be used when therapy beyond the period covered by the first prescription is needed, but these are generally discouraged. For schedule III and IV drugs, refills may be issued either orally or in writing, not to exceed five refills or 6 months after the issue date, whichever comes first. Beyond this time, a new prescription must be ordered. For schedule V drugs, there are no restrictions on the number of refills allowed, but if no refills are noted at the time of issuance, a new prescription must be made for additional drug to be dispensed.

**Preventing Diverion**

Prescription blanks often are stolen and used to sustain abuse of controlled substances. To prevent this type of diversion, prescription pads should be...
protected in the same manner as one would protect a personal checkbook. A prescription blank should never be presigned for a staff member to fill in at a later time. Also, a minimum number of pads should be stocked, and they should be kept in a locked, secure location. If a pad or prescription is missing, it should be reported immediately to local authorities and pharmacies. Ideally, the physician’s full DEA number should not be preprinted on the prescription pad because anyone in possession of a valid DEA number may find it easier to commit prescription fraud. Some physicians may intentionally omit part or all of their DEA number on a prescription and instead write “pharmacist call to verify” or “call for registration number.” This practice works only when the pharmacist may independently verify the authenticity of the prescription, and patients must fill the prescription during the prescriber’s office hours. Pharmacists can ascertain the authenticity of a physician’s DEA number using an algorithm.

Another method employed by the drug seeker is to alter the face of a valid prescription to increase the number of units or refills. By spelling out the number of units and refills authorized instead of giving numerals, the prescriber essentially removes this option for diversion. Controlled substances should not be prescribed excessively or for prolonged periods, as the continuance of a patient’s addiction is not a legitimate medical purpose.

**Weed**

Twenty-nine U.S. states and the District of Columbia have placed marijuana, classified by the FDA as a schedule 1 substance, in a special category by decriminalizing its possession and sale for medical use. In these jurisdictions, patients and caregivers are exempt from prosecution by state law, contrary federal law notwithstanding. Nine of these jurisdictions, AL, CA, CO, MA, ME, NV, OR, WA, and the District of Columbia—permit the possession of marijuana for recreational use. This legal difference of opinion between state and federal regulation is the source of considerable controversy (Leyton, 2016). Generally, the most stringent law takes precedence, whether it is federal, state, or local.

**The Prescription as a Commodity**

Prescribers must be aware that patients may visit their doctor to “get” a prescription. In many patient-physician interactions, a prescription can be seen as the currency or mandatory product of the visit. Physicians must educate each patient about the importance of viewing medicines as something to be used only when really needed, and that remaining on a particular medicine when in stable condition may be preferable to seeking the newest medications available. The federal FDA Modernization Act of 1997 permits the use of print and television advertising of prescription drugs. The law requires that all drug advertisements contain (amongst other things) summary information relating to side effects, contraindications, and effectiveness. The benefits of these types of DTC advertising are controversial (Mintzes, 2012). Prescription drug advertising has alerted consumers to the existence of new drugs and the conditions they treat, but it has also increased consumer demand for drugs. This demand has increased the number of prescriptions being dispensed (raising sales revenues) and has contributed to the higher pharmaceutical costs borne by health insurers, government, and consumers. In the face of a growing demand for particular brand-name drugs driven by advertising, physicians and pharmacists must be able to counsel patients effectively and provide them with evidence-based drug information.

**The Special Case of Seniors**

Seniors represent just over 14% of the population, but consume 40% of prescription drugs and 35% of all over-the-counter drugs. On average, individuals 65 to 69 years old take nearly 14 prescriptions per year; individuals aged 80 to 84 take an average of 18 prescriptions per year; 15% to 25% of drug use in seniors is considered unnecessary or otherwise inappropriate (Hwang et al., 2001). Adverse drug reactions are more common in the elderly and, together with noncompliance, are responsible for 28% of hospitalizations of the elderly, at a cost exceeding $180 billion annually. Each year, 32,000 seniors suffer hip fractures caused by medication-related problems (Iuga and McGuire, 2014).

**Drug Standards and Classification**

The U.S. Pharmacopeial Convention, Incorporated, is a nongovernmental organization that disseminates authoritative standards and information on medicines and other healthcare technologies. This organization is home to the USP, which, together with the FDA, the pharmaceutical industry, and health professions, establishes authoritative drug standards. These standards are enforceable by the FDA and governments of other countries and are recognized worldwide. Drug monographs are published in the USP/NF; the official drug standards compendia that organize drugs into categories based on pharmacological actions and therapeutic uses. The USP also provides chemical reference standards to carry out the tests specified in the USP/NF. For example, a drug to be manufactured and labeled in units must comply with the USP standard for units of that compound. Such standards are essential for agents possessing biological activity, such as insulin or antibody-based medications.

The USP also is home to the USP Dictionary of U.S. Adopted Names (USAN) and International Drug Names. This compendium is recognized throughout the healthcare industry as the authoritative dictionary of drugs. Entries include one or more of the following: U.S. Adopted Names, official drug names for the NF, previously used official names, International Nonproprietary Names, British Approved Names, Japanese Accepted Names, trade names, and other synonyms. In addition to names, the records in this file contain other substance information, such as CAS, RN, molecular formula, molecular weight, pharmacological or therapeutic category, drug sponsor, reference information, and structure diagram, if available. The USP maintains an electronic website that can be accessed for useful information on drug naming, classification, and standards (http://www.usp.org).

In the U.S., drug products also are coded under the NDC. The NDC serves as a universal product identifier for drugs used in humans. The current edition of the NDC Directory is limited to prescription drugs and a few selected over-the-counter products. Each drug product listed under the Federal Food, Drug, and Cosmetic Act is assigned a unique 10-digit, 3-segment number. This number, the NDC number, identifies the labeler/vendor, product, and package size. The labeler/vendor code is assigned by the FDA. The second segment, the product code, identifies a specific strength, dosage form, and formulation for a particular drug company. The third segment, the package code, identifies package sizes. Both the product and package codes are assigned by the manufacturer. In addition to classification of drugs by therapeutic category, drugs also are grouped by control schedule. Drug schedules in the U.S. are listed in Box AI–1 and discussed under Controlled Substances.

The FDA also categorizes drugs that may be used in pregnant women. These categories are similar to those used in other countries and provide guidance based on available science. The categories range from A to X, in increasing order of concern:

- **Pregnancy Category A**: Adequate and well-controlled studies have failed to demonstrate a risk to the fetus in the first trimester of pregnancy (and there is no evidence of risk in later trimesters). Because of the obvious nature of the risk associated with the use of medications during gestation, the FDA requires a body of high-quality data on a drug before it can be considered for Pregnancy Category A.

- **Pregnancy Category B**: Animal reproduction studies have failed to demonstrate a risk to the fetus, and there are no adequate and well-controlled studies in pregnant women. Drugs in this category include levotyroxine and folic acid.

- **Pregnancy Category C**: Animal reproduction studies have shown an adverse effect on the fetus, and there are no adequate and well-controlled studies in pregnant women. OR animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester. Drugs in this category include metformin and hydrochlorothiazide and should be prescribed only as needed for maternal health.

- **Pregnancy Category D**: Animal reproduction studies have shown an adverse effect on the fetus, and there are no adequate and well-controlled studies in pregnant women.
studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks. Drugs in this category include tramadol and gabapentin. They should be prescribed in pregnancy only when benefit clearly outweighs risk.

- **Pregnancy Category D:** There is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience or studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks. Drugs in this category, such as alprazolam and clonazepam, are not recommended for use during pregnancy and should be prescribed in pregnancy only if absolutely necessary.

- **Pregnancy Category X:** Studies in animals or humans have demonstrated fetal abnormalities or there is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience, and the risks involved in use of the drug in pregnant women clearly outweigh potential benefits. Drugs such as warfarin, methotrexate, and statins fall into this category and must not be used during pregnancy or in women likely to become pregnant.

Physicians should realize that the pregnancy categories by themselves provide little guidance for the physician treating pregnant women. Prescribers must understand the embryology, physiology, and pharmacology involved in each instance of drug use during pregnancy. For example, ACE inhibitors such as captopril cause developmental toxicity (category X), but only after the first trimester. A physician’s primary responsibility remains treating the pregnant patient. However, the risks of withholding treatment to the mother because of possible risks to the fetus have to be considered as well. The practitioner should rely on medical evidence when making these decisions.

Drugs also are grouped by their potential for misuse under British and U.N. legal classifications as class A, B, or C. The classes are linked to maximum legal penalties in a descending order of severity, from A to C.

### Compliance

Compliance is the extent to which the patient follows a regimen prescribed by a healthcare professional. The patient is the final and most important determinant of how successful a therapeutic regimen will be and should be engaged as an active participant who has a vested interest in its success. Whatever term is used—compliance, adherence, therapeutic alliance, or concordance—physicians must promote a collaborative interaction between doctor and patient in which each brings an expertise that helps to determine the course of therapy. The patient’s quality-of-life beliefs may differ from the clinician’s therapeutic goals, and the patient will have the last word every time when there is an unresolved conflict.

Hundreds of variables that may influence compliance behavior have been identified. A few of the most frequently cited are in Box AI–2, along with some suggestions for improving compliance, although none guarantees 100% compliance.

Noncompliance may be manifest in drug therapy as intentional or accidental errors in dosage or schedule, overdose, underuse, early termination of therapy, or not having a prescription filled; therapeutic failures can result (Malek and Grosset, 2015). Noncompliance always should be considered in evaluating potential causes of inconsistent or nonexistent response to therapy. The reported incidence of patient noncompliance usually is in the range of 30%–60%; the rate for long-term regimens is about 50% and can be improved by medication management (Klein et al., 2009).

### The Patient-Provider Relationship

Patient satisfaction with the physician has a significant impact on compliance behavior. Patients are more likely to follow instructions and recommendations when their expectations for the patient-physician relationship and for their treatment are met. These expectations include not only clinical but also interpersonal and communication skills; thus, cultivating good interpersonal and communication skills is essential.

---

**BOX AI–2 Suggestions for Improving Patient Compliance**

- Provide respectful communication; ask how patient takes medicine.
- Develop satisfactory, collaborative relationship between physician and patient; encourage pharmacist involvement.
- Provide and encourage use of medication counseling.
- Give precise, clear instructions, with most important information given first.
- Support oral instructions with easy-to-read written information.
- Simplify whenever possible.
- Use mechanical compliance aids as needed (sectioned pillboxes or trays, compliance packaging, color coding).
- Use optimal dosage form and schedule for each individual patient.
- Assess patient’s literacy, language, and comprehension and modify educational counseling as needed. Be culturally aware and sensitive. To improve compliance, don’t rely on patient’s own knowledge of disease alone.
- Find solutions when physical or sensory disabilities are present (use nonsafety caps on bottles, use large type on labels and written material, place tape marks on syringes).
- Enlist support and assistance from family and caregivers.
- Use behavioral techniques such as goal setting, self-monitoring, cognitive restructuring, skills training, contracts, and positive reinforcement.

When deciding on a course of therapy, it can be useful to discuss a patient’s habits and daily routine as well as the therapeutic options with the patient. This information may suggest cues for remembrance. A lack of information about a patient’s lifestyle can lead to situations such as prescribing a medication to be taken with meals three times daily for a patient who only eats twice a day or a medication to be taken each morning for a patient who works a night shift and sleeps during the day. Rarely is there only one treatment option for a given problem, and it may be better to prescribe an adequate regimen that the patient will follow instead of an ideal regimen that the patient will not. Attempts should be made to resolve collaboratively any conflicts that may hinder compliance. Whenever possible, the family should be aware of the physician’s treatment plan in order to assist with compliance.

### Patients and Their Beliefs

Patients are more likely to be compliant when they perceive that they are susceptible to the disease, that the disease may have serious negative impact, that the therapy will be effective, that the benefits outweigh the costs, and when they believe in their own ability to execute the therapy. The actual severity of and susceptibility to an illness are not necessarily an issue; rather, the patient’s perception of severity affects compliance. Patients’ beliefs can lead them to deliberately alter their therapy, whether for convenience, for personal experiments, because of a desire to remove themselves from the sick role, as a means to exercise a feeling of control over their situation, or for other reasons. This reinforces the need for precise communication and a good patient-provider relationship to facilitate the provision of additional or corrective education when the beliefs would suggest poor compliance as an outcome (Hsiao et al., 2012; Nieuwlaat et al., 2014).

Pharmacists have a legal and professional responsibility to offer medication counseling and can educate and support patients by discussing prescribed medications and their use. Because they often see the patient more frequently than does the physician, pharmacists who take the time to inquire about a patient’s therapy can help identify compliance and other problems, educate the patient, and notify the physician as appropriate (Phatak et al., 2016). Indeed, data from the Asheville Project indicates that a pharmacist-based medication management program provides significant advantages with respect to compliance, health outcomes, and cost (Bunting and Cranor, 2006).
Elderly patients often face a number of barriers to compliance related to their age: increased forgetfulness and confusion; altered drug disposition and higher sensitivity to some drug effects; decreased social and financial support; decreased dexterity, mobility, or sensory abilities; and the use of a greater number of concurrent medicines (both prescription and over the counter) whose attendant toxicities and interactions may cause decreased mental alertness or intolerable side effects. There are drugs known to be inappropriate to prescribe to elderly patients and some that may adversely affect compliance (Aparasu and Mort, 2000). Despite these obstacles, evidence does not show that elderly patients in general are significantly less compliant than any other age group. Physicians must be careful in choosing medications for the elderly. Pharmacists must pay particular attention to thorough and compassionate counseling for elderly patients and should assist patients in finding practical solutions when problems, such as polypharmacy, are noted (Mansur, 2016).

**The Therapy**

Increased complexity and duration of therapy are perhaps the best-documented barriers to compliance. The patient for whom multiple drugs are prescribed for a given disease or who has multiple illnesses that require drug therapy will be at higher risk for noncompliance, as will the patient whose disease is chronic. The frequency of dosing of individual medications also can affect compliance behavior. Simplification, whenever possible and appropriate, is desirable. The effects of the medication can make adherence less likely, as in the case of patients whose medicines cause confusion or other altered mental states. Unpleasant side effects from the medicine may influence compliance in some patients, but are not necessarily predictive, especially if patient beliefs or other positive factors tend to reinforce adherence to the regimen. A side effect that is intolerable to one patient may be of minor concern to another. The cost of medicine can be a heavy burden for patients with limited economic resources, and healthcare providers should be sensitive to this fact (Restrepo et al., 2008). Mobile phones and tablets running drug formulary/therapeutic applications can provide the costs of medications, as can physicians who are familiar with the patient’s insurance plan. Mobile phone systems and wearables that provide reminders and collect patient response information and physiological data are being introduced and may become more popular as patients and providers become increasingly tech savvy (Parmanto et al., 2013). Such technology may soon be capable of carrying patient genetic information that may become increasingly tech savvy (Parmanto et al., 2013). Such technology may soon be capable of carrying patient genetic information that may assist the physician in choosing medications based on knowledge of a patient’s ability to metabolize a specific drug efficiently or that such treatment may interfere with an existing treatment (Weiss and Shin, 2016). Effective treatments that do not produce unwanted effects will improve compliance.

**Electronic Prescribing**

The era of e-prescribing eliminates some of the subjective features of prescribing. Thus, if the proper information is entered correctly in the electronic system, medication errors due to illegible handwriting, incorrect dose, incorrect medication for medical condition, and drug interactions can be reduced because each prescription can be linked to high-quality drug databases that check that the information on the prescription is appropriate for the patient (e.g., age, weight, gender, condition, laboratory values, disease being treated, concurrent medications) and that known warnings and potential problems are brought to the attention of the physician, pharmacist, and patient. Such systems must not be used as a substitute for personal attention to the individual patient by healthcare workers but rather as an adjunct measure that ensures safe, high-quality, efficient care. Sadly, the participation of human beings in the process has not eliminated errors, even in the university hospital setting (Al Tehewy et al., 2016). Physicians and pharmacists must remember that only when the seriousness of their mutual responsibilities are front and center in their minds will patient safety be ensured.

**BOX AI–3 Prescribing Practices to Avoid Adverse Drug Events**

- Write all orders legibly using metric measurements of weight and volume.
- Include patient age and weight on the prescription, when appropriate, so dosage can be checked.
- Use Arabic (decimal) numerals rather than Roman numerals (e.g., does “IL–II” mean “IL-11” or “IL-2”?), in some instances, it is preferable for numerals to be spelled out.
- Use leading zeros (0.125 milligrams, not .125 milligrams); never use trailing zeros (5 milligrams, not 5.0 milligrams).
- Avoid abbreviating drug names; abbreviations may lead to misinterpretation.
- Avoid abbreviating directions for drug administration; write out directions clearly in English.
- Be aware of possibilities for confusion in drug names. Some drug names sound alike when spoken and may look alike when spelled out. The U.S. Pharmacopeial Convention Medication Errors Reporting Program maintains a current list of 750 drug names that can be confused (http://www.usp.org). Alliterative drug names can be particularly problematic when giving verbal orders to pharmacists or other healthcare providers.
- Provide the patient’s diagnosis on the prescription order to prevent dispensing errors based on sound-alike or look-alike drug names. For example, an order for administration of magnesium sulfate must not be abbreviated “MS,” as this may result in administration of morphine sulfate. Including the therapeutic purpose or the patient’s diagnosis can prevent this error.
- Write clearly. Both physician and pharmacist share in the responsibility for preventing adverse drug events by writing prescriptions clearly (When in doubt, write it out!) and questioning intent whenever an order is ambiguous (When in doubt, check it out!). Pharmacists must clarify their concerns with prescribers, not patients.
- Think.
- Think again.

**Eliminating Errors in Drug Orders**

The IOM estimates that the annual number of medical errors in the U.S. that result in death is between 44,000 and 98,000 (Kohn, 2001). Although there is some controversy about these estimates, it is clear that the large number of medical errors includes medication errors resulting in adverse events, including death. Databases of anonymously reported errors are maintained jointly by the ISMP, the USP MERP, and the FDA’s MedWatch program. Adverse drug events occur in about 3% of hospitalizations, and this number is larger for special populations, such as those in pediatric and neonatal intensive care units. By examining aspects of prescription writing that can cause errors and then modifying prescribing habits accordingly, the physician can increase the probability that the patient will receive the correct prescription. By being alert to common problems that can occur with medication orders and communicating with the patient’s physician, pharmacists and other healthcare professionals can assist in reducing medication errors. Proper prescribing practices (Box AI–3) can help to prevent adverse drug events.

**Bibliography**

Bunting BA, Cranor CW. The Asheville Project: long-term clinical, humanistic, and economic outcomes of a community-based medication...

This page intentionally left blank
This appendix provides a summary of basic pharmacokinetic information pertaining to small-molecule drugs that are in common clinical use and are delivered to the systemic circulation by parenteral or nonparenteral administration. Because of space limitations, this list cannot be exhaustive. Drugs designed exclusively for topical administration and not to be significantly absorbed into the bloodstream (e.g., ophthalmic and some dermal applications; Chapters 69 and 70) are not included. A few other selection criteria have influenced the makeup of the list, but, in general, the authors have tried to include one or more representative drugs in each of the therapeutic areas in this text, based on distinct mechanism(s) of action. In some instances, drugs may be excluded because pharmacokinetics are not relevant to their therapeutic management. An obvious case is when drug efficacy is not apparently correlated with drug concentration in a reversible fashion (e.g., some cytotoxic anticancer drugs).

Often, the issue comes down to deciding which of the many drugs within a class should be selected. This is particularly problematic when the choices are largely therapeutic equivalents. Two criteria that have proven useful are prevalence of use and uniqueness of mechanism of action. For the present edition, we have consulted the top 200 selling drugs in 2015 for usage data. Drugs that fall into that list and meet the criteria mentioned were generally selected. We have also consulted all new FDA drug approvals between 2010 and 2015. As mentioned, a drug used less may be included if it has a different mechanism of action than the frequently used drugs, some additional actions that offer a unique therapeutic advantage, or a more acceptable side-effects profile. Pharmacokinetic data for many older drugs not included in this appendix can be found in earlier editions of this book.

With rare exceptions (e.g., interferons), recombinant therapeutic proteins have been excluded from this compilation. In many cases, the therapeutic protein is directed to interact with specific tissue or cellular targets with exquisite affinity; as a result, clinical efficacy seldom correlates with circulating drug concentration, and pharmacokinetics are not considered critical in guiding its dosing. For example, for a number of therapeutic antibodies, the antibody is administered at a fixed dose at prolonged intervals that allow for its near-complete clearance (e.g., infliximab). There is again the constraint of space limitation; hence, it was decided that the appendix should focus on small-molecule drugs.

A major objective of this appendix is to present pharmacokinetic data in a format that informs the clinician of the essential characteristics of drug disposition that form the basis of drug-dosage regimen design. Table AII–1 contains quantitative information about the absorption, distribution, and elimination of drugs; the effects of some disease states, age, pregnancy, and gender on these processes, where significant; and the correlation of efficacy and toxicity with drug concentrations in blood/plasma. The general principles that underlie the design of appropriate maintenance dose and dosing interval (and, where appropriate, the loading dose) for the average patient are described in Chapter 2. Their application using the data in Table AII–1 for individualization of dosage regimens is presented here.

To use the data that are presented, one must understand clearance concepts and their application to drug-dosage regimens. One also must know average values of clearance as well as some kinetic measures of drug absorption and distribution. The text that follows defines the eight basic parameters that are listed in the tabular material for each drug and key factors that influence these values in both normal subjects and patients with renal or liver disease. Obviously, it would be more straightforward if there were a consensus on a standard value for a given pharmacokinetic parameter; instead, literature estimates usually vary over a wide range, and a consensus set of pharmacokinetic values has been reached for only a limited number of drugs.

In Table AII–1, a single set of values for each parameter and its variability in a relevant population has been selected from the literature, based on the scientific judgment of the authors. Most data are in the form of a study population mean value ± 1 standard deviation (mean ± SD). However, some data are presented as mean and range of values (in parentheses) observed for the study population (i.e., the lowest and highest value reported). There are times when data are reported as a geometric mean with a 95% confidence interval or a coefficient of variation (in percentage). If sufficient data were available, we present a range of mean values obtained from different studies of similar design in parentheses, sometimes below the primary study data. Occasionally, only a single mean value for the study population was available in the literature and is reported as such. Finally, some drugs can be administered intravenously in an unmodified form and orally as a prodrug. When relevant information about both the prodrug and the active molecule are needed, we have included both, using an abbreviation to indicate the species that was measured, followed by another abbreviation in parentheses to indicate the species that was dosed [e.g., G (V) indicates a parameter for ganciclovir after administration of the prodrug, valganciclovir].

A number of approved drugs are actually the active metabolite or stereoisomer of an earlier marketed drug. For example, desloratadine is the O-desmethyl metabolite of loratadine, and esomeperazone is the active S-enantiomer of omeprazole. Unless the parent drug and the active metabolite offer distinct therapeutic advantages, only the more established or more commonly used drug is listed, and relevant information on its alternate active form is presented in the same table. This approach has
permit us to include more drugs in the appendix, it is hoped without undue confusion. The only exception is with prednisone and prednisolone, which undergo interconversion in the body.

Unless otherwise indicated in footnotes, data reported in the table are those determined in healthy adults. The direction of change for these values in particular disease states is noted below the average value. In previous editions, we have included disease states where studies have shown no change or clinically insignificant change for a particular pharmacokinetic measure. For the sake of space and consistency, we have eliminated the results of negative studies; hence, when a disease state is not listed, it implies no significant change or no information is available. One or more references are provided for each of the established drugs, typically an original journal publication, a review on its clinical pharmacokinetics, or web-based drug database; the last two secondary sources provide a broader range of papers for the interested reader. In some instances (e.g., many new drug approvals), we have relied on unpublished data provided by the drug sponsor in its NDA files or package labeling submitted to the U.S. FDA. This information can be accessed at Drugs@FDA: FDA Approved Drug Products (https://www.accessdata.fda.gov/scripts/cder/daf/). After searching by drug name, pharmacokinetic data are found most often in the Clinical Pharmacology and Biopharmaceutics section. Recent standardization in the presentation of data supporting the NDA in this section makes this an increasingly valuable resource.

### Tabulated Pharmacokinetic Parameters

Each of the eight parameters presented in Table AII–1 was discussed in detail in Chapter 2. The following discussion focuses on the format in which the values are presented as well as on physiological or pathological factors that influence the parameters.

#### Bioavailability

The *extent of oral bioavailability* is expressed as a percentage of the administered dose. This value represents the percentage of the administered dose that is available to the systemic circulation—the fraction of the oral dose that reaches the arterial blood in an active or prodrug form, expressed as a percentage (0–100). Fractional availability \( F \), which appears elsewhere in this appendix, denotes the same parameter; this value varies from 0 to 1. \( t_{\text{av}} \) is a measure of the *rate of availability* and is also presented in the table. The extent of availability is needed for the design of an oral dosage regimen to achieve a specific target blood concentration. Values for multiple routes of administration are provided, when appropriate and available. In most cases, the tabulated value represents an absolute oral bioavailability that has been determined from a comparison of AUC between the oral dose and an intravenous reference dose. For those drugs for which intravenous administration is not feasible, an approximate estimate of oral bioavailability based on secondary information (e.g., urinary excretion of unchanged drug, especially when the nonrenal route of elimination is minimal) is presented, or the column is left blank (denoted by a long dash [—]). A dash also will appear when a drug is given by parenteral administration only. A low oral bioavailability may result from a poorly formulated dosage form that fails to disintegrate or dissolve in the gastrointestinal fluid; has degradative loss of drug in the gastrointestinal fluid; has poor mucosal permeability, including active efflux transport of drug back into the lumen; has first-pass metabolism during transit through the intestinal epithelium; or there is first-pass hepatic metabolism or biliary excretion (see Chapter 2). In the case of drugs with extensive first-pass metabolism, hepatic disease may increase oral availability because hepatic metabolic capacity decreases or because vascular shunts develop around the liver.

### Urinary Excretion of Unchanged Drug

The second parameter in Table AII–1 is the amount of drug eventually excreted unchanged in the urine, expressed as a percentage of the administered dose. Values represent the percentage expected in a healthy young adult (creatinine clearance ≥ 100 mL/min). When possible, the value listed is that determined after bolus intravenous administration of the drug, for which bioavailability is 100%. If the drug is given orally, this parameter may be underestimated due to incomplete absorption of the dose; such approximated values are indicated with a footnote. The parameter obtained after intravenous dosing is of greater utility because it reflects the fractional contribution of renal clearance to total body clearance irrespective of bioavailability.

Renal disease is the primary factor that causes changes in this parameter. This is especially true when alternate pathways of elimination are available; thus, as renal function decreases, a greater fraction of the dose is available for elimination by other routes. Because renal function generally decreases as a function of age, the percentage of drug excreted unchanged also decreases with age when alternate pathways of elimination are available. In addition, for a number of weakly acidic and basic drugs with \( pK_a \) values within the normal range for urine pH, changes in urine pH will affect their rate or extent of urinary excretion (see Chapter 2).

#### Binding to Plasma Proteins

The tabulated value is the percentage of drug in the plasma that is bound to plasma proteins at concentrations of the drug that are achieved clinically. In almost all cases, the values are from measurements performed in vitro (rather than from ex vivo measurements of binding to proteins in plasma obtained from patients to whom the drug had been administered). When a single mean value is presented, it signifies that there is no apparent change in percentage bound over the range of plasma drug concentrations resulting from the usual clinical doses. In cases in which saturation of binding to plasma proteins is approached within the therapeutic range of plasma drug concentrations, a range of bound percentages is provided for concentrations at the lower and upper limits of the range. For some drugs, there is disagreement in the literature about the extent of plasma-protein binding; in those cases, the range of reported values is given.

Plasma-protein binding is affected primarily by disease states, notably hepatic disease, renal impairment, and inflammatory diseases, that alter the concentration of albumin, \( a_1 \)-acid glycoprotein, or other proteins in plasma that bind drugs. Uremia also changes the apparent binding affinity of albumin for some drugs. Disease-induced changes in plasma-protein binding can dramatically affect the volume of distribution, clearance, and elimination \( t_{\text{av}} \) of a drug. In regard to clinical relevance, it is important to assess the change in unbound drug concentration or AUC, particularly when only unbound drug can cross biological barriers and gain access to the site of action.

#### Plasma Clearance

Systemic clearance of total drug from plasma or blood (see Equations 2–4, 2–5, and 2–7 in Chapter 2) is given in Table AII–1. Clearance varies as a function of body size and therefore most frequently is presented in the table in units of milliliters/minute/kilogram of body weight. Normalization to measures of body size other than weight may at times be more appropriate, such as normalization to body surface area in infants to better reflect the growth and development of the liver and kidneys. However, weight is easy to obtain, and its use often offsets any small loss in accuracy of clearance estimate, especially in adults. Exceptions to this rule are the anticancer drugs, for which dosage normalization to body surface area is
conventionally used. When unit conversion was necessary, we used individual or mean body weight or body surface area (when appropriate) from the cited study, or if this was not available, we assumed a body mass of 70 kg or a body surface area of 1.73 m² for healthy adults.

For the few drugs that exhibit saturation kinetics following therapeutics doses, $K_m$ and $V_{max}$ are given and represent, respectively, the plasma concentration at which half of the maximal rate of elimination is reached (in units of mass/volume) and the maximal rate of elimination (in units of mass/time/kilogram of body weight). $K_e$ must be in the same units as the concentration of drug in plasma ($C_d$).

In almost all cases, clearances based on plasma concentration data are presented in Table AII–1 because drug analysis most often is performed on plasma samples. The few exceptions where clearance from blood is presented are indicated by footnote. Clearance estimates based on blood concentration may be useful when a drug concentrates in the blood cells.

To be accurate, clearances must be determined after intravenous drug administration. When only nonparenteral data are available, the ratio of CL/F is given; values offset by the fractional availability $F$ are indicated in a footnote. When a drug, or its active isomer for racemic compounds, is known to be a substrate for a CYP or drug transporter, this information is provided in a footnote. This information is important for understanding pharmacokinetic variability due to genetic polymorphisms and for predicting metabolically based drug-drug interactions, although these factors are beyond the scope of this table. For clinically relevant pharmacogenetic information, the reader is referred to CPIC Guidelines listed on the PharmGKB website (https://www.pharmgkb.org/). The reader is referred to a comprehensive database for drug-drug interaction information (DIDIB) (https://www.druginteractioninfo.org/). The former site is open access, whereas the latter can be accessed by a licensing agreement.

**Volume of Distribution**

The total body volume of distribution at steady state $V_s$ is given in Table AII–1 and is expressed in units of liters/kilogram or in units of liters/square meter for some anticancer drugs. Again, when unit conversion was necessary, we used individual or mean body weights or body surface area (when appropriate) from the cited study, or if such data were not available, we assumed a body mass of 70 kg or a body surface area of 1.73 m² for healthy adults.

When estimates of $V_s$ were not available, values for $V_{ss}$ are provided; $V_{ss}$ represents the volume at equilibrated distribution during the terminal elimination phase. Unlike $V_s$, $V_{ss}$ varies when drug elimination changes, even though there is no change in extravascular distribution. Because we may wish to know whether a particular disease state influences either the clearance or the tissue distribution of the drug, it is preferable to define the volume in terms of $V_s$, a parameter that is less likely to depend on changes in the rate of elimination. Occasionally, the condition under which the distribution volume was obtained was not specified in the primary reference; this is denoted by the absence of a subscript.

As with clearance, $V_s$ usually is defined in the table in terms of concentration in plasma rather than blood. Further, if data were not obtained after intravenous administration of the drug, a footnote will make clear that the apparent volume estimate, $V_s/F$ or $V_{ss}/F$, is offset by the fractional availability.

**Half-Life**

Half-life $t_{1/2}$ is the time required for the plasma concentration to decline by one-half when elimination is first order. It also governs the rate of approach to steady state and the degree of drug accumulation during multiple dosing or continuous infusion. For example, at a fixed dosing interval, the patient will be at 50% of steady state after one half-life, 75% of steady state after two half-lives, 93.75% of steady state after four half-lives, and so on. Determination of $t_{1/2}$ is straightforward when drug elimination follows a monoeponential pattern (i.e., one-compartment model). However, for a number of drugs, plasma concentration follows a multieponential pattern of decline over time. The mean value listed in Table AII–1 corresponds to an effective rate of elimination that covers the clearance of a major fraction of the absorbed dose from the body. In many cases, this $t_{1/2}$ refers to the rate of elimination in the terminal exponential phase. For a number of drugs, however, the $t_{1/2}$ of an earlier phase is presented, even though a prolonged $t_{1/2}$ may be observed later at very low plasma concentrations when extremely sensitive analytical techniques are used. If the latter component accounts for 10% or less of the AUC, predictions of drug accumulation in plasma during continuous or repetitive dosing will be in error by no more than 10% if this longer $t_{1/2}$ is ignored. Equation 2–19 in Chapter 2 provides for an estimate of the effective $t_{1/2}$ that predicts time to steady state for multicompartmental drug kinetics. It is this $t_{1/2}$ of accumulation during multiple dosing that is given in Table AII–1. Half-life is usually independent of body size because it is a function of the ratio of two parameters, clearance and volume of distribution, each of which is proportional to body size. It also should be noted that the $t_{1/2}$ is preferably obtained from intravenous studies, if feasible, because the $t_{1/2}$ of decline in plasma drug concentration after oral dosing can be influenced by prolonged absorption, such as when slow-release formulations are given. If the $t_{1/2}$ is derived from an oral dose, this will be indicated in a footnote of Table AII–1.

**Time to Peak Concentration**

Because clearance concepts are used most often in the design of multiple-dosage regimens, the extent rather than the rate of availability is more critical to estimate the average steady-state concentration of drug in the body. In some circumstances, the degree of fluctuation in plasma drug concentration (i.e., peak and trough concentrations), which govern drug efficacy and side effects, can be greatly influenced by modulation of drug absorption rate through the use of sustained- or extended-release formulations. Controlled-release formulations often permit a reduction in dosing frequency from three or four times daily to once or twice daily. There also are drugs that are given on an acute basis (e.g., for the relief of breakthrough pain or to induce sleep), for which the rate of drug absorption is a critical determinant of onset of effect. Thus, information about the expected average time to achieve maximal plasma or blood concentration and the degree of interindividual variability in that parameter have been included in Table AII–1.

The time required to achieve a maximal concentration $t_{max}$ depends on the rate of drug absorption into blood from the site of administration and the rate of elimination. From mass balance principles, $t_{max}$ occurs when the rate of absorption equals the rate of elimination from the reference compartment. Prior to this time, absorption rate exceeds elimination rate, and the plasma concentration of drug increases. After the peak is reached, elimination rate exceeds the absorption rate and, at some point, defines the terminal elimination phase of the concentration-time profile. The rate of drug absorption following oral administration will depend on the formulation and physicochemical properties of the drug, its permeability across the mucosal barrier, and the intestinal villous blood flow. For an oral dose, some absorption may occur very rapidly within the buccal cavity, esophagus, and stomach, or absorption may be delayed until the drug reaches the small intestine or until the local pH in the intestine permits drug release from the dosage formulation. In the most extreme case, the rate of absorption can be sufficiently controlled by the drug formulation to permit sustained or extended delivery as the dosage form traverses the entire length of the gastrointestinal tract. In some instances, the terminal elimination of drug from the body following a peak concentration reflects the slower rate of absorption and not elimination.

When more than one type of drug formulation is available commercially, we provide absorption information for both the immediate- and extended-release formulations. Not surprisingly, the presence of food in the gastrointestinal tract can alter both the rate and the extent of drug absorption. Not surprisingly, the presence of food in the gastrointestinal tract can alter both the rate and the extent of drug absorption. Not surprisingly, the presence of food in the gastrointestinal tract can alter both the rate and the extent of drug absorption. Not surprisingly, the presence of food in the gastrointestinal tract can alter both the rate and the extent of drug absorption.

**Peak Concentration**

There is no general agreement about the best way to describe the relationship between the concentration of drug in plasma and its effect. Many different kinds of data are present in the literature, and use of a single-effect
parameter or effective concentration is difficult. This is particularly true for antimicrobial agents because the effective concentration depends on the identity of the microorganism causing the infection. It also is important to recognize that concentration-effect relationships are most easily obtained at steady state or during the terminal log-linear phase of the concentration-time curve, when the drug concentration(s) at the site(s) of action are expected to parallel those in plasma. Thus, when attempting to correlate a blood or plasma level to effect, the temporal aspect of distribution of drug to its site of action must be taken into account.

Despite these limitations, it is possible to define the minimum effective or toxic concentrations for some of the drugs currently in clinical use. However, in reviewing the list of drugs approved within the past 5 years, it is rare to find a declaration of an effective concentration range, even in the manufacturer's package labeling. Thus, it is necessary to infer therapeutic concentrations from concentrations observed following effective dosage regimens. For a given dosage regimen, a time-averaged steady-state blood or plasma concentration (i.e., $C_{ss}$ as estimated by dividing the mean AUC by the duration of the dosing interval) and the associated interindividual variability might be one appropriate parameter to report; however, such data often are not available. Also, $C_{ss}$ does not take into account the onset and offset of effect during fluctuation of plasma drug concentration over a dosing interval. In some instances, drug efficacy may be more closely linked with peak concentration than with the average or trough concentration, and differences in peak concentration for special populations (e.g., elderly) sometimes are associated with increased incidence of drug toxicity.

For practical reasons, the most commonly reported parameter, $C_{max}$ (peak concentration), rather than effective or toxic concentrations, is presented in Table AII–1. This provides a more consistent body of information about drug exposure from which one can infer, if appropriate, efficacious or toxic blood levels. Although the value reported is the highest that would be encountered in a given dose interval, $C_{max}$ can be related to the trough concentration $C_{min}$ through appropriate mathematical predictions (see Equation 2–20 in Chapter 2). Because peak levels will vary with dose, we have attempted to present concentrations observed with a customary dose regimen that is recognized to be effective in the majority of patients. When a higher or lower dose rate is used, the expected peak level can be adjusted by assuming dose proportionality, unless nonlinear kinetics are indicated. In some instances, only limited data pertaining to multiple dosing are available, so single-dose peak concentrations are presented. When specific information is available about an effective therapeutic range of concentrations or about concentrations at which toxicity occurs, it has been incorporated in a footnote.

It is important to recognize that significant differences in $C_{max}$ will occur when comparing similar daily-dose regimens for an immediate-release and extended-release product. Indeed, the extended-release product sometimes is administered to reduce peak-trough fluctuations during the dosing interval and to minimize swings between potentially toxic or ineffective drug concentrations. Again, we report $C_{min}$ for both immediate- and extended-release formulations, when available. In addition to parent drug concentrations, we have included information on any active metabolite that circulates at a concentration that may contribute to the overall pharmacological effect, particularly those active metabolites that accumulate with multiple dosing. Likewise, for chiral drugs whose stereoisomers differ in their pharmacological activity and clearance characteristics, we present information on concentrations of the individual enantiomers or the active enantiomer that contributes most to the drug's efficacy.

### Alterations of Parameters in the Individual Patient

Dose adjustments for an individual patient should be made according to the manufacturer's recommendation in the package labeling when available. This information generally is available when disease, age, or race has a significant impact on drug disposition, particularly for drugs that have been introduced within the past 15 years. In some cases, a significant difference in drug disposition from the "average" adult can be expected but may not require dose adjustment because of a sufficiently broad therapeutic index. In other cases, dose adjustment may be necessary, but no specific information is available. Under these circumstances, an estimate of the appropriate dosage regimen can be obtained based on pharmacokinetic principles described in Chapter 2.

Unless otherwise specified, the values in Table AII–1 represent mean values for populations of normal adults; it may be necessary to modify them for calculation of dosage regimens for individual patients. The fraction available $F$ and clearance $CL_{ss}$ would need to be adjusted to compute a maintenance dose necessary to achieve a desired average steady-state concentration. To calculate the loading dose, knowledge of the volume of distribution is needed. The estimated $t_{1/2}$ is used in deciding a dosing interval that provides an acceptable peak-trough fluctuation; note that this may be the apparent $t_{1/2}$ following dosing of a slowly absorbed formulation. The values reported in the table and the adjustments apply only to adults; exceptions are footnoted. Although the values at times may be applied to children who weigh more than about 30 kg (after proper adjustment for size; see Clearance and Volume of Distribution, presented in the following material), it is best to consult pediatric textbooks or other sources for definitive advice.

For each drug, changes in the parameters caused by certain disease states are noted within the eight segments of the table. In all cases, the qualitative direction of changes is noted, such as "$↓$ LD," which indicates a significant decrease in the parameter in a patient with chronic liver disease. The relevant literature and the package label should be consulted for more definitive, quantitative information for dosage adjustment recommendations.

### Plasma Protein Binding

Most acidic drugs that are extensively bound to plasma proteins are bound to albumin. Basic lipophilic drugs, such as propranolol, often bind to other plasma proteins (e.g., $\alpha$-acid glycoprotein and lipoproteins). The degree of drug binding to proteins will differ in pathophysiological states that cause changes in plasma protein concentrations. Significant pharmacokinetic effects from a change in plasma protein binding are denoted under clearance or volume of distribution.

Although pharmacokinetic parameters based on total drug or metabolite concentrations often are reported, it is important to recognize that in many cases it is the concentration of unbound drug that drives access to the site of action and the degree of pharmacological effect. Remarkable changes in the total plasma concentration may accompany disease-induced alteration in protein binding; however, the clinical outcome is not always affected because an increase in free fraction also will increase the apparent clearance of an orally administered drug and of a low-extraction drug dosed intravenously. Under such a scenario, the time-averaged unbound plasma concentration over a dosing interval at steady state will not change with reduced or elevated plasma protein binding, despite a significant change in time-averaged total drug concentration. If so, no adjustment of daily maintenance dose is needed.

### Clearance

For drugs that are partly or predominantly eliminated by renal excretion, plasma clearance changes in accordance with the renal function of an individual patient. This necessitates dosage adjustment that is dependent on the fraction of normal renal function remaining and the fraction of drug normally excreted unchanged in the urine. The latter quantity appears in the table; the former can be estimated as the ratio of the patient's estimated or measured creatinine clearance $CL_{cr}$ to a normal value (100 mL/min/1.73 m$^2$). Because urinary creatinine clearance is not routinely measured, it is often estimated from standardized serum creatinine concentration $C_{cr}$ using the MDRD Study equation for $CL_{cr}$ less than 60 mL/min/1.73 m$^2$.

$$CL_{cr} \text{ (mL/min/1.73 m}^2\text{)} = 175 \times \left(\frac{C_{cr}}{1.73}\right)^{1.154} \times \left(\frac{\text{Age}}{1.212}\right) \times \left(0.743 \text{ if female} + 0.728 \text{ if African American}\right) \text{ (Equation A–1)}$$

Note that Equation A–1 does not require body weight as the $CL_{cr}$ estimate is normalized to average adult body surface; proportionate
scaling is needed for adjustment to different body surface area. Convenient calculators are available for the MDRD equation and the CKD-EPI equation for more accurate estimation of $CL_{cr}$ greater than 60 mL/min/1.73 m² (e.g., https://www.niddk.nih.gov/health-information/health-communication-programs/nkdep/lab-evaluation/gfr/estimating/Pages/estimating.aspx).

The fraction of normal renal function $r_{fx,pt}$ is estimated from the following:

$$r_{fx,pt} = \frac{CL_{cr,pt}}{100 \text{ mL/min}}$$

(Equation A–2)

A more accurate measure of $r_{fx}$ seldom is necessary because, given the considerable degree of interindividual variation in nonrenal clearance, the adjustment of clearance is an approximation. The following equation for adjustment of clearance uses the quantities discussed:

$$rf_{pt} = 1 - [fe_{pt} \cdot (1 - rf_{x,pt})]$$

(Equation A–3)

where $fe_{pt}$ is the fractional systemic drug excreted unchanged in normal individuals (see Table AII–1). The renal factor $rf_{x,pt}$ is the value that, when multiplied by normal total clearance $CL_{cr,pt}$ from the table, gives the total clearance of the drug adjusted for the impairment in renal function.

**Example**

The clearance of vancomycin in a patient with reduced renal function (creatinine clearance = 25 mL/min for an average-size adult) may be estimated as follows:

$$rf_{x,pt} = \frac{25 \text{ mL/min}}{100 \text{ mL/min}} = 0.25$$

$$fe_{pt} = 0.79 \text{ (see listing for vancomycin)}$$

$$rf_{pt} = 1 - [0.79 \cdot (1 - 0.25)] = 0.41$$

$$CL_{pt} = (1.3 \text{ mL/min/kg}) \times 0.41$$

$$= 0.53 \text{ mL/min/kg}$$

Importantly, such a clearance adjustment should be regarded only as an initial step in optimizing the dosage regimen; depending on the patient’s response to the drug, further individualization may be necessary.

Conventionally, clearance is adjusted for the size of the patient to reflect a difference in the mass of the eliminating organ. For orally administered drugs, the applicability of such an adjustment may be limited by the available dosage strengths of commercial formulations. In some cases, scored tablets can be split, or commercial tablet splitters are used to increase the range of available dosage strengths. However, this practice should be followed only with the recommendation of the pharmacist because splitting tablets sometimes can compromise the bioavailability of a product.

With the exception of certain oncolytic agents, the data presented in the table are normalized to weight. Thus, interindividual variability in the weight-normalized clearance reflects a variation in the intrinsic metabolic or transport clearance and not the size of the organ. Further, these differences can be attributed to variable expression/function of metabolic enzymes or transporters. However, it is important to recognize that liver mass and total enzyme/transporter content may not increase or decrease in proportion to weight in obese or malnourished individuals. Alternative approaches such as normalization by body surface area or other measures of body mass may be more appropriate. For example, many of the drugs used to treat cancer are dosed according to body surface area (see Chapters 65 and 66). In the tabulation, if the literature reported dose per body surface area, we present the data in the same unit. If the cited clearance data were not normalized, but the preponderance of the literature utilized body surface area, we followed the practice of using values of body surface area from the literature source or a standard of 1.73 m² for a healthy adult.

**Volume of Distribution**

Volume of distribution should be adjusted for the modifying factors indicated in Table AII–1 as well as for body size. Again, the data in the table most often are normalized to weight. Unlike clearance, volume of distribution in an individual usually is proportional to weight itself. Whether this applies to a specific drug depends on the actual sites of distribution of drug; no absolute rule applies.

Whether to adjust volume of distribution for changes in binding to plasma proteins cannot be decided in general; the decision depends critically on whether the factors that alter binding to plasma proteins also alter binding to tissue proteins. Qualitative changes in volume of distribution, when they occur, are indicated in the table.

**Half-Life**

Half-life may be estimated from the adjusted values of clearance $CL_{pt}$ and volume of distribution $V_{pt}$ for the patient:

$$t_{1/2} = \frac{0.693 \cdot V_{pt}}{CL_{pt}}$$

(Equation A–4)

Because $t_{1/2}$ has been the parameter most often measured and reported in the literature, qualitative changes for this parameter almost always are given in the table.

**Individualization of Dosage**

By using the parameters for the individual patient, calculated as described in the previous section, initial dosing regimens may be chosen. The maintenance dosage rate may be calculated with Equation 2–21 and estimates for $V_{ss}$ and $F$. A particular dosing interval may be chosen; the maximal and minimal steady-state concentrations can be calculated by using Equations 2–20, and these calculated concentrations can be compared with the known efficacious and toxic concentrations for the drug. As with the target concentration, these values may need to be adjusted for changes in the extent of plasma protein binding. Use of Equations 2–20 and 2–21 also requires estimates of values for $F$, $V_{ss}$, and $K$ ($= 0.693/t_{1/2}$) for the individual patient.

Note that these adjustments of pharmacokinetic parameters for an individual patient are suggested for the rational choice of initial dosing regimen. As indicated in Chapter 2, steady-state measurement of drug concentrations in the patient then can be used as a guide to further adjust the dosage regimen. However, optimization of a dosage regimen for an individual patient ultimately will depend on the clinical response produced by the drug.
#### Table AII–1  ■ Pharmacokinetic Data

**Key:** Unless otherwise indicated by a specific footnote, the data are presented for the study population as a mean value ± 1 standard deviation, a mean and range (lowest-highest in parentheses) of values, a range of the lowest-highest values, or a single mean value. ACE, angiotensin-converting enzyme; Aged, aged; AIDS, acquired immunodeficiency syndrome; C<sub>max</sub>, peak concentration; CYP, cytochrome P450; F or Fem, female; HIV, human immunodeficiency virus; IM, intramuscular; IV, intravenous; LD, chronic liver disease; M, male; MAO, monoamine oxidase; NAT, N-acetyltransferase; Neo, neonate; Obes, obesity; PDR54, Physicians’ Desk Reference, 54th ed. Montvale, NJ, Medical Economics Co., 2000; PDR58, Physicians’ Desk Reference, 58th ed. Montvale, NJ, Medical Economics Co., 2004; PDR59, Physicians’ Desk Reference, 59th ed. Montvale, NJ, Medical Economics Co., 2005; Prem, premature infants; Rac, racemic mixture of stereoisomers; RD, chronic renal disease; SC, subcutaneous; Smk, smoking; ST, sulfortransferase; T<sub>1/2</sub>, peak time; UGT, UDP-glucuronosyl transferase. Other abbreviations are defined in the text section of this appendix.

*Metabolically cleared by CYP3A. †Provides adequate anesthesia for superficial surgery. ‡Provides adequate anesthesia for abdominal surgery.

### Aliskiren

- Absolute bioavailability of 75 mg in hard gelatin capsule reported. Oral AUC decreased 71% with high-fat meal.
- Aliskiren is cleared by both renal excretion and CYP3A-dependent hepatic metabolism; however, the relative contribution of each pathway to total drug clearance is unclear.
- Study in patients with moderate-to-severe liver impairment; systemic exposure increased 1.0- to 2.5-fold but was independent of disease severity.
- Following a 10-mg dose of extended-release formulation given once a day for 5 days.

### Allopurinol

- Data from healthy male and female subjects. Allopurinol (A) is rapidly metabolized to the pharmacologically active oxypurinol (O). *Increased oxypurinol AUC during renal impairment and in the elderly.* Following a single 300-mg oral dose.

### Alprazolam

- Metabolically cleared by CYP3A and other cytochrome P450 isozymes. *Data from male subjects only.* Mean (range) from 19 studies following a single 1-g oral dose given to adults.

### Amiodarone

- Significant plasma concentrations of an active desethyl metabolite are observed (ratio of drug/metabolite ~ 1); t½ for metabolite ~ 61 days. *Metabolically cleared by CYP3A.

Longer t½ noted in patients (53 ± 24 days), all reported t½ may be underestimated because of insufficient length of sampling. *Following a 400-mg/d oral dose to steady state in adult patients.*

*Data for amphotericin B shown. aData for eight children (ages 8 months to 14 years) yielded a linear regression, with CL decreasing with age: CL = –0.046 · Age (years) + 0.86.

References:

- Amphotericin distribution and properties of these products are different from the nonencapsulated form; they have a terminal $t_{1/2}$ of 173 ± 78 and 110–153 h, respectively; however, an effective steady-state concentration can be achieved within 4 days; $t_{1/2}$ for multiple dosing.

- A1/2 is 94 h. No significant gender differences. $t_{1/2}$ after oral dose is ~ 12 h because of slow absorption. Following a single 5-mg oral dose to 16 healthy adults.

References:

- The major metabolite, dehydro-aripiprazole, has affinity for D2 receptors similar to parent drug; found at 40% of parent drug concentration in plasma; $t_{1/2}$ is 94 h. No significant gender differences. Eliminated primarily by CYP2D6- and CYP3A4-dependent metabolism. CYP2D6 poor metabolizers exhibit increased exposure (80%) to parent drug but reduced exposure (30%) to the active metabolite. CL/F and V/F at steady state reported. Following a 15-mg oral dose given once daily for 14 days.

- Following a 400-mg oral dose given with a light meal once daily to steady state.

- Phosphokinetic data reported for healthy adults. No significant gender or age differences. Absolute bioavailability is not known, but food enhances the extent of absorption.

- Following a single 50-mg oral dose. CL/F unchanged during pregnancy; however, renal clearance of atenolol is increased during pregnancy.

</tbody>
</table>

1Data from healthy adult male and female subjects. No clinically significant gender differences. Atorvastatin undergoes extensive CYP3A-dependent first-pass metabolism. Metabolites are active and exhibit a longer t1/2 (20 to 30 h) than parent drug. Mean CL/F calculated from reported AUC data at steady state after a once-a-day 20-mg oral dose, assuming a 70-kg body weight. AUC following oral administration increased, mild-to-moderate hepatic impairment. Following a 20 mg oral dose, once daily, for 14 days.

</tbody>
</table>

*Bupropion is administered as a racemic mixture of R and S bupropion that can interconvert. Data from healthy adult male volunteers. Bupropion is metabolized by CYP2B6 to hydroxy-bupropion and by 11β-hydroxysteroid dehydrogenase and aldo-ketoreductases to three- and erythrohydrobupropion. All three metabolites accumulate in blood and are active. CL/F, Vd/F, and t1/2 reported for oral dose. Percentage coefficient of variation shown in parentheses. Following oral dosing of 150-mg XL (sustained release) tablet to 42 healthy subjects for 7 days (steady state). 95% confidence interval shown in brackets.

**Buspirone** | 3.9 ± 4.3 | <0.1 | >95 | 28.3 ± 10.3 | 5.3 ± 2.6 | 2.4 ± 1.1 | 0.71 ± 0.06 | 1.66 ± 0.21 ng/mL |
| **Calcitriol** | 70 (44–94) | 1 | 2.7–14 | 4.5 ± 0.9 | 0.99 ± 0.23 | 2.6 ± 0.5 | 2.6 ± 1.5 | Low: 65 ± 27 ng/mL |

*CL/F and Vd/F reported. Following a single 4-mg oral dose (low) given to patients with chronic myelocytic leukemia or a single 1-mg/kg oral dose (high) given as ablative therapy to patients undergoing bone marrow transplantation.

**Calcitriol** | PO: –61 | <10% | 99.9 | 0.43 ± 0.04 | — | 16.5 ± 3.1 | PO: 3–6 | IV: –460 pg/mL |
| **Calcitriol** | IP: –67 | <10% | 99.9 | 0.43 ± 0.04 | — | 16.5 ± 3.1 | PO: 3–6 | IV: –460 pg/mL |

*Data from young (15–22 years) patients on peritoneal dialysis. Metabolized by 23-, 24-, and 26-hydroxylases and also excreted into bile as its glucuronide. Calcitriol t1/2 is 5–8 h in healthy adult subjects. Oral dose t1/2 = 27 ± 12 h, children 2–16 years. Following a single 60-ng/kg IV, intraperitoneal (IP), or oral dose. Baseline plasma levels were < 10 pg/mL. Following a single 60-ng/kg IV, intraperitoneal (IP), or oral dose. Baseline plasma levels were < 10 pg/mL.

**Canagliflozin** | 65 | <1 | 98–99 | 2.74[a] | 1.70[a] | 6.9[a] | 1.5 (1–5) | 1227 ± 481 ng/mL |

*Calculated as the ratio of canagliflozin renal clearance/total intravenous clearance. Following oral dosing of 150-mg XL (sustained release) tablet to 42 healthy subjects for 7 days to patients with type 2 diabetes mellitus.

**Candesartan** | 42 (34–56) | 52 | 99.8 | 0.37 (0.31–0.47) | 0.13 (0.09–0.17) | 9.7 (4.8–13) | 4.0 ± 1.3 | 119 ± 43 ng/mL |

*Data from healthy adult male subjects. Candesartan cilexetil is rapidly and completely converted to candesartan through the action of gut wall esterases. Mean (range) for candesartan reported. No significant gender or age differences. CL/F reduced mild-to-severe renal disease. Mean (SD) following a 16-mg oral dose (tablet) daily for 7 days.

*Data from male and female patients with cancer. Carboplatin (C) is a prodrug for 5-fluorocytosine (5-FU, active), listed further in this table. It is well absorbed, and bioactivation is sequential in liver and tumor. *AUC for C and 5-FU decreased. *Geometric mean (coefficient of variation). *CL/F and V₁/F reported for oral dose. *Following 1255 mg/m².

**Carbamazepine**

| 78 ± 24b | 3 | 74 ± 6 | 0.73 ± 0.3b | 1.1 ± 0.3b | 20 ± 9b | — | 11.2–11.7 (2–18) μg/mLb |

*Metabolite, carbamazepine-10,11-epoxide, is equipotent in animal studies. Its formation is catalysed primarily by CYP2A6 and secondarily by CYP3A. It is mainly excreted in the urine as the active metabolite with minor excretion as unchanged drug. *Data from healthy adult subjects. Combined with levodopa for treatment of Parkinson disease. *Absolute bioavailability is unknown, but it is presumably low based on a high value for CL/F. Bioavailability of Sinemet CR (S-CR) is 55% of standard Sinemet (S). *CL/F and V₁/F reported for tablets of Sinemet 25/100. *Following a single oral dose of 2 tablets Sinemet 25/100 or 1 tablet Sinemet CR 50/200.

**Carbidopa**

| 5.3 ± 2.1 | — | 18 ± 7c | — | — | 2.1 ± 1.0 | S: 165 ± 77 ng/mLd |

*Kinetic measurements for ultrafilterable platinum, which essentially is unchanged carboplatin. *Following a single 170- to 500-mg/m² IV dose (30-min infusion) given to adult patients with ovarian cancer.

**Carvedilol**

| 25 | <2 | 95b | 8.7 ± 1.7 | 1.5 ± 0.3 | 2.2 ± 0.3c | 1.3 ± 0.3d | 105 ± 12 ng/mLd |

*Racemic mixture: S(-)-enantiomer responsible for β1 adrenergic–receptor blockade. R(+)- and S(-)-enantiomers have nearly equivalent α1 receptor blocking activity. *R(+)-enantiomer is more tightly bound than the S(-)-antipode. *Longer t¹/₂ of ~ 6 h has been measured at lower concentrations. *Following a 12.5-mg oral dose given twice a day for 2 weeks to healthy young adults.

1Active metabolite, desethylchloroquine, accounts for 20% ± 3% of urinary excretion; t½c = 15 ± 6 days. 2Racemic mixture; kinetic parameters for the two isomers are slightly different, CL/F = 116 mL/min and 237 mL/min and V/F = 3410 L and 4830 L for the R-isomer and S-isomer, respectively. 3Range of mean values from different studies (intravenous administration). 4Concentrates in red blood cells. Blood-to-plasma concentration ratio for racemate = 9. 5A longer t½c (41 ± 14 days) has been reported with extended blood sampling. 6Following a single 300-mg IV dose (24-min infusion) of chloroquine HCl or a single 300-mg IM or oral dose of chloroquine phosphate given to healthy adults. Effective concentrations against Plasmodium vivax and Plasmodium falciparum are 15 µg/mL and 30 µg/mL, respectively. Diaporia and dizziness can occur > 250 ng/mL.

**Chlorpromazine**

</tbody>
</table>

1Active metabolite, 7-hydroxychlorpromazine (t½c = 25 ± 15 h) and possibly chlorpromazine N-oxide, yield AUCs comparable to the parent drug (single doses). 2After a single dose. Bioavailability may decrease to ~ 20% with repeated dosing. 3CL/F, Vc, and terminal t½c following intramuscular administration. 4Following a 100-mg oral dose given twice a day for 33 days to adult patients. Neurotoxicity (tremors and convulsions) occurs at concentrations of 750–1000 ng/mL.

**Chlorothalidone**

* Cinacalcet is a chiral molecule; the R-enantiomer is more potent than the S-enantiomer and is thought to be responsible for the drug’s pharmacological activity. Cinacalcet is metabolized primarily by CYP3A4, CYP2D6, and CYP1A2. Unreported, but presumably negligible. Following a single 75-mg oral dose.

Table AII–1 continued.

Clonidine is cleared via renal route and CYP2D6-mediated hydroxylation. Mean data following a 0.1-mg oral dose given twice a day to steady state or steady-state concentration (C_s) following a 3.5-cm² transdermal (TD) patch administered to normotensive male adults. Concentrations of 0.2–2 ng/mL are associated with a reduction in blood pressure; >1 ng/mL will cause sedation and dry mouth.

enhancing the systemic exposure of Clo following oral administration. The reported value may represent disappearance of high levels of metabolite formed during first pass and not the terminal t₁/₂, which should be formation limited. Following a single 300-mg loading dose of Clo.

*Clopidogrel (Clo) is a prodrug that is converted to a minor unstable active metabolite (AM) via two sequential cytochrome P450–dependent reactions. The majority of the dose is converted rapidly to an inactive hydrolytic product by esterases. Although multiple P450 isozymes contribute to the formation of AM, blood levels of AM have been associated with the CYP2C19 genotype and phenotype status, with poor metabolizers (PM) exhibiting lower levels, on average, than extensive metabolizers (EM). Formation of AM accounts for ≤ 10% of the administered dose and may be dose dependent due to saturable metabolism. The absolute bioavailability of Clo is unknown. There is one report of food greatly enhancing the systemic exposure of Clo following oral administration. The reported value may represent disappearance of high levels of metabolite formed during first pass and not the terminal t₁/₂, which should be formation limited. Following a single 300-mg loading dose of Clo.

</table>

- Lanoxin tablets, digoxin solutions, elixirs, and capsules are absorbed more completely. 19% of the dose is excreted into bile and into feces following intravenous administration. Intestinal and renal excretion of digoxin is mediated by P-glycoprotein and other digoxin specific transporters. Following an oral dose of 0.31 ± 0.19 mg/d in patients with congestive heart failure who exhibited no signs of digitalis toxicity.

#### Diltiazem*  
38 ± 11  
<4  
78 ± 3  
11.8 ± 2.2b  
3.3 ± 1.2  
4.4 ± 1.3c  
4.0 ± 0.4d  
151 ± 46 ng/mLd  

- Active metabolites, desacetyldiltiazem (t1/2 = 9 ± 2 h) and N-desmethyl diltiazem (t1/2 = 7.5 ± 1 h). Formation of desmethyl metabolite (major pathway of CL) catalyzed primarily by CYP3A. More than a 2-fold decrease with multiple dosing. t1/2 for oral dose is 5–6 h, does not change with multiple dosing. Following a single 120-mg oral dose to healthy adults.

#### Docetaxela  
2.1 ± 0.2  
94  
22.6 ± 7.7 L/h/m2  
72 ± 24 L/m2  
13.6 ± 6.1  
—  
2.4 ± 0.9 µg/mLc  

- Data from male and female patients treated for cancer. Metabolized by CYP3A and excreted into bile. Parenteral administration. Mild-to-moderate liver impairment. Following an intravenous infusion of 85 mg/m2 over 1.6 h.

#### Donepezil*  
10.6 ± 2.7  
92.6 ± 0.9b  
2.90 ± 0.74c  
14.0 ± 2.42c  
59.7 ± 16.1e  
3–4f  
30.8 ± 4.2 ng/mLg  

- Data from young, healthy male and female subjects. No significant gender differences. Absolute bioavailability is unknown. A fraction bound value of 96% also has been reported. Metabolically cleared by CYP2D6, CYP3A4, and UGT. CL/F and V/F calculated assuming 70-kg body weight; mean (CV%) reported for single oral dose to healthy volunteers. t1/2, reported for oral dose. CL/F reduced slightly (~20%), alcoholic cirrhosis. Following a 5-mg oral dose given once daily to steady state.

#### Dolutegravirk  
98.9  
0.27 (45)c  
0.33 (45)c  
14.4 (19)c  
2–3  
4.15 (29) µg/mLc  

- Absolute oral bioavailability is not known. Cleared from blood predominantly by UGT1A1–dependent metabolism. CL/F and V/F calculated assuming 70-kg body weight; mean (CV%) reported for single oral dose to healthy volunteers. t1/2, reported for patients with HIV-1 infection. Mean plasma concentration (CV%) in HIV-1 infected patients receiving 50-mg dolutegravir, twice a day, to steady state.

#### Dolutegravir  
Y: 65 ± 14  
5  
Y: 1.26 ± 0.27b  
E: 1.0 ± 0.1  
20.5 ± 6.1d  
3.9 ± 1.2  
67 ± 19 ng/mLc  

- Where indicated, data for young (Y) and elderly (E) normotensive adults are reported. Also reported are data for a gastrointestinal sustained-release device (GITS), Cardura XL (extended release), oral bioavailability relative to standard formulation (Fss), Cleared primarily by cytochrome P450–dependent metabolism. Study in patients with mild-to-moderate liver impairment. AUC increased 43%. Shorter t1/2, following intravenous dosing reported. (Y) 10 ± 1 h, (E) 12 ± 5 h, attributed to inadequate duration of blood sampling. Following an 8-mg dose of standard formulation or GITS, once daily, to steady state in young and elderly normotensive volunteers.

↑ RD  

<sup>1</sup>Enoxaparin consists of low-molecular-weight heparin fragments of varying lengths.  
<sup>2</sup>43% is recovered in urine when administered as 99Tc-labeled enoxaparin; 8%–20% anti–factor Xa activity.  
<sup>3</sup>Calculated from a 25-mg IV dose assuming 0.75–1.5<sup>e</sup> kg of body weight.  
<sup>4</sup>M: 2.0–2.8<sup>d</sup>  
<sup>5</sup>Cleared primarily by CYP3A-dependent metabolism.  
<sup>6</sup>Study in patients with mild-to-moderate hepatic impairment.  
<sup>7</sup>Following single 20–80-mg oral doses; MF: migraine-free period; M: during a migraine attack. Range of mean values from different studies following a single 30-mg oral dose.  
<sup>8</sup>Systemic exposure increased 20%–30% with high-fat meal.  
<sup>9</sup>Data from 50–mg/kg IV dose reported; lack of dose proportionality for oral AUC between 20- and 80- or 80-mg doses.  
<sup>10</sup>Cleared primarily by CYP3A-dependent metabolism.  
<sup>11</sup>Study in patients with mild-to-moderate hepatic impairment.  
<sup>12</sup>Following single 20–80-mg oral doses; MF: migraine-free period; M: during a migraine attack. Value for subcutaneous dose measured by functional assay for anti–factor Xa activity. BCLM, below-critical-length molecules (anti–factor Xa activity).  
<sup>13</sup>Measured by functional assay of anti–factor Xa activity. Using anti-IIa activity or displacement binding assay gives a t<sub>1/2</sub> of ~1–2 h.  
<sup>14</sup>Following a single 40-mg SC dose to healthy adult subjects.  
<sup>15</sup>High-affinity antithrombin III molecules: ACLM, above-critical-length molecules (anti–factor Xa and IIa activity); BCLM, below-critical-length molecules (anti–factor Xa activity).  
<sup>16</sup>See also Section 12.8.  
<sup>17</sup>EPR: 5–20 ng/mL.  
<sup>18</sup>Reported.  
<sup>19</sup>Recovery of unchanged drug (<2%) after an oral dose.  
<sup>20</sup>Erlotinib is cleared primarily by CYP3A- and CYP1A2-dependent metabolism.  
<sup>21</sup>Calculated from a 25-mg IV dose assuming a 70-kg body weight.  
<sup>22</sup>Median t<sub>1/2</sub> of 36 h was reported for a single 25-mg IV dose.  
<sup>23</sup>Following 150-mg oral dose given once daily to steady state.  
<sup>25</sup>EPR: 5–20 ng/mL.  
<sup>26</sup>Reported.  
<sup>27</sup>Recovery of unchanged drug (<2%) after an oral dose.  
<sup>28</sup>Erlotinib is cleared primarily by CYP3A- and CYP1A2-dependent metabolism.  
<sup>29</sup>Calculated from a 25-mg IV dose assuming a 70-kg body weight.  
<sup>30</sup>Median t<sub>1/2</sub> of 36 h was reported for a single 25-mg IV dose.  
<sup>31</sup>Following 150-mg oral dose given once daily to steady state.

* Esomeprazole is the S-enantiomer of omeprazole. Both esomeprazole (Es) and racemic omeprazole (Rac) are available. Data for both formulations are reported. † Bioavailability determined after multiple dosing. Lower Es values 64% (54%–75%) reported for single dose. †† The metabolic CL of the Es is slower than that of the R-enantiomer. Both Es and Rac are metabolized by CYP2C19 (polymorphic) and CYP3A4. CL of Es and Rac is decreased and t1/2 increased in CYP2C19 poor metabolizers. †† Following a single 40-mg IV dose. CL of Es decreases and t1/2 of Es increases with multiple dosing. † Reduced CL and increased t1/2 in patients with severe (Childs-Pugh class C) hepatic impairment. †† Following a 40-mg oral dose of Es given once daily for 5 days to healthy subjects of unspecified CYP2C19 phenotype. †† Following a 20-mg oral dose of Rac given twice daily for 4 days to healthy subjects phenotyped as CYP2C19 extensive metabolizers (EM) and poor metabolizers (PM).

**Eszopiclone,a Zopiclone**

| Es: <10 | Es: 52–59 | — | — | Es: 7.2 ± 1.3 | Es: 1 (0.4–2.1) | Es: 39.8 ± 8.6 ng/mL* |
|——|——|——|——|——|——|——|

* Eszopiclone is the (S)-isomer of zopiclone. Pharmacokinetic data after dosing of eszopiclone (Es) is shown. Es is metabolized extensively by CYP3A4 and CYP2E1. † CL/F following a 15-mg oral dose of zopiclone is 2.7 mL/min/kg for Es and 4.4 mL/min/kg for racemic zopiclone. †*F* Following a 15-mg oral dose of racemic zopiclone is 1.4 L/kg for eszopiclone and 2.1 L/kg for racemic zopiclone. †† In patients with severe hepatic impairment. †† Following a 3-mg Es given once daily to steady state.

**Ethambutol**

| 77 ± 8 | 79 ± 3 | 6–30 | 8.6 ± 0.8 | 1.6 ± 0.2 | 3.1 ± 0.4 | 2–4* | 2–5 μg/mL* |
|——|——|——|——|——|——|——|——|

* Following a single 800-mg oral dose to healthy subjects. Concentrations > 10 μg/mL can adversely affect vision. No accumulation with once-a-day dosing in patients with normal renal function.

*Decreases at oral doses greater than 200 mg. †Decreases with hyperbilirubinemia. •Metabolized by CYP3A; also a substrate for P-glycoprotein. •Mean Cmax for patients without (NT) and with (T) serious hematological toxicity following a 75- to 200-mg/m² dose given as a 72-h continuous intravenous infusion.

Exenatide is a synthetic peptide cleared primarily by the kidney through filtration, reabsorption, and proteolytic degradation. *CL/F after SC injection reported. \(V_{\text{UR}}/F\) after SC injection reported. †Following a 10-μg SC injection.

Ezetimibe is extensively metabolized to a glucuronide, which is more active than ezetimibe in inhibiting cholesterol absorption. Clinical effects are related to the total plasma concentration of ezetimibe and ezetimibe glucuronide, with ezetimibe concentrations being only 10% of the total. *For ezetimibe and ezetimibe glucuronide. †CL/F and a volume for the central compartment (\(V_{\text{C}}\)) for total (unconjugated and glucuronide conjugate) ezetimibe reported. §Ezetimibe undergoes significant enterohepatic recycling, leading to multiple secondary peaks. An effective \(t_{\text{1/2}}\) is estimated. ‡Total (unconjugated and glucuronide conjugate) ezetimibe following a 10-mg oral dose given once daily for 10 days.

Famotidine is a prodrug that is hydrolyzed by esterases to fenofibric acid, the pharmacologically active compound. All values reported are for fenofibric acid. *Metabolized by CYP3A-dependent first-pass metabolism in the intestine and liver: Following a 200-mg oral immediate-release (IR) or extended-release (ER) tablet given twice daily to steady state in healthy subjects. BCR for diastolic pressure decrease is 8 ± 5 nM in patients with hypertension.

*Data from patients with leukemia. Rapidly metabolized intracellularly to active di- and triphosphate products; intravenous administration. 1cWeight-normalized CL is ~ 25% lower in women, compared to men. Vm and t1/2 are reported to increase with long duration of intravenous infusion. 1sSteady-state concentration during a 10-mg/m²/min infusion for 120–640 min.

| **Gemfibrozil**            |                      |                     |                       |                  |                  |                |                   |
| 98 ± 1                    | <1                   | 97                  | 1.7 ± 0.4*            | 0.14 ± 0.03      | 1.1 ± 0.2        | 1–2b          | 15–25 μg/mLb     |

*Gemfibrozil is mainly cleared by UGT2B7-dependent glucuronidation. Both gemfibrozil and gemfibrozil glucuronide inhibit CYP2C8 and organic anion transport protein (OATP) 1B1 and OATP1B3. 1bFollowing a 600-mg oral dose given twice daily to steady state.

| **Gentamicin**             |                      |                     |                       |                  |                  |                |                   |
| IM: ~100                  | >90                  | <10                 | 0.62 ± 0.16           | 0.31 ± 0.10      | 2–3b            | IV: 1c         | IV: 4.9 ± 0.5 μg/mLc |
| Aged                      | —                    |                     |                       |                  |                  |                |                   |

*Gentamicin clearance declines in proportion to a decline in CLcr. 1cGentamicin has a very long terminal t1/2 of 53 ± 25 h (slow release from tissues), which accounts for urinary excretion for up to 3 weeks after a dose. Majority of the dose is eliminated during the distribution phase. 1bFollowing a single 100-mg IV infusion (1 h) or IM injection given to healthy adults.

| **Glimepiride**            |                      |                     |                       |                  |                  |                |                   |
| −100                      | <0.5                 | >99.5               | 0.62 ± 0.26           | 0.18             | 3.4 ± 2.0        | 2–3c          | 359 ± 98 ng/mLc  |
| Aged                      | —                    |                     |                       |                  |                  |                |                   |

*Data from healthy male subjects. No significant gender differences. Glimepiride is metabolized by CYP2C9 to an active (approximately one-third potency) metabolite, M1. 1cCL/F, Vm/F increased and t1/2 prolonged in patients with type 2 diabetes mellitus. M1 is reported to increase in plasma free fraction. M1 AUC also increased. 1bFollowing a single 3-mg oral dose.

| **Glipizide**              |                      |                     |                       |                  |                  |                |                   |
| 95                        | <5                   | 98.4                | 0.52 ± 0.18           | 0.17 ± 0.02*     | 3.4 ± 0.7        | 2.1 ± 0.9b     | 465 ± 139 ng/mLb |

<CL/F and Vm/F reported. 1bFollowing a single 5-mg oral dose (immediate-release tablet) given to healthy young adults. An extended-release formulation exhibits a delayed T1/2 of 6–12 h.

| **Glyburide**              |                      |                     |                       |                  |                  |                |                   |
| G: 90–100a                | Negligible           | 99.8                | 1.3 ± 0.5             | 0.20 ± 0.11      | 4 ± 1b          | ▲ LD          | M: 106 ng/mLc    |
| M: 64–90a                 | ▼ Aged               | ▼ LD                |                       |                  |                  |                |                   |

*Data for Glycine Prestop micronized tablet (G) and Micronase tablet (M). 1bFor micronized formulation reported. t1/2 for nonmicronized formulation is 6 to 10 h, reflecting absorption rate limitation. A long terminal t1/2 (15 h), reflecting redistribution from tissues, has been reported. Longer t1/2 in patients with type 2 diabetes mellitus also reported. 1bFollowing a 3-mg oral Glycine tablet taken with breakfast or a 5-mg oral Micronase tablet given to healthy adult subjects.

*Racemic mixture. Kinetic parameters for the active S-(−)-enantiomer do not differ from those for the inactive R-(−) enantiomer when administered separately. 63 ± 6% of the R-(−)-enantiomer undergoes inversion to the active isomer. †Unbound percent of S-(−)-ibuprofen (0.77 ± 0.20%) is significantly greater than that of R-(−)-ibuprofen (0.45 ± 0.06%). Binding of each enantiomer is concentration dependent and is influenced by the presence of the optical antipode, leading to nonlinear elimination kinetics. ‡CL/F and V/F reported. ††Following a single 800-mg dose of racemate. A level of 10 μg/mL provides antipyresis in febrile children.

*Active metabolite of isosorbide dinitrate. Following a 20-mg oral dose given by asymmetric dosing (0 and 7 h) for 4 days.

References: Abshagen UW. Pharmacokinetics of isosorbide mononitrate. Am J Cardiol, 1992, 70:64G–66G.

| **Isotretinoin** | | | | | | | |
| 40a | Negligible | >99 | 5.5 (0.9–11.1)c | 5 (1–32)c | 17 (5–167)c | I: 4.5 ± 3.4c | 4-oxo: 6.8 ± 6.5c |
| ↑ Food | | | | | | | 4-oxo: 473 ± 171 ng/mLc |

*Isotretinoin (I) is eliminated through metabolic oxidations catalyzed by multiple CYPs (2C8, 2C9, 3A4, and 2B6). The 4-oxo-isotretinoin metabolite (4-oxo) is active and found at higher concentrations than parent drug at steady state. Bioavailability when taken with food is reported. CL/F and V/F reported. 4-oxo has an apparent mean t1/2 of 29 ± 6 h.

Values for I and 4-oxo following a 30-mg oral dose given once daily to steady state.

| **Itraconazole** | | | | | | | |
| 55 | <1 | 99.8 | 5.1a | 10.7a | 21 ± 6e | 3–5f | 649 ± 289 ng/mLf |
| ↑ Foodb | | | | | | | |

*Metabolized predominantly by CYP3A4 to an active metabolite, hydroxyitraconazole, and other sequential metabolites. Relative to oral dosing with food. Blood CL is 9.4 mL/min/kg. CL is concentration dependent; the value given is nonsaturable range. CL/F = 330 ± 200 mg/mL, V/F = 2.2 ± 0.8 mg · mL⁻¹ · min⁻¹ · kg⁻¹. Apparent CL/F at steady state reported to be 3.4 mL · min⁻¹ · kg⁻¹. V/F reported. Follows multicompartment kinetics. Does not appear to be concentration dependent. t1/2 reported for oral dose. Terminal t1/2, reported.

Following a single 150-μg/kg oral dose.

| **Ivermectina** | | | | | | | |
| — | <1 | 93.1 ± 0.2 | 2.06 ± 0.81c | 9.91 ± 2.67c | 56.5 ± 7.5c | 4.7 ± 0.5c | 38.2 ± 5.8 ng/mLc |
| ↑ Foodb | | | | | | | 351 ± 289 ng/mLb |

*Data from male and female patients treated for onchocerciasis. Bioavailability when taken with food is reported. CL/F and V/F reported. 4-oxo has an apparent mean t1/2 of 29 ± 6 h.

Values for I and 4-oxo following a 30-mg oral dose given once daily to steady state.

| **Ivermectin** | | | | | | | |
| 30–65b | — | 50 | 23 ± 5.3c | 9.9 ± 1.5 | 8.3–1.4d | 1.5–2e | 274 ± 99 ng/mLf |

*The clinical formulation of ivermectin consists of equal proportions of 4 optical isomers. Bioavailability correlates with age and increases with age. Bioavailability appears to increase with multiple dosing. 1/2 reported for oral dose. Terminal t1/2 reported.

Following a 200-mg oral dose given daily for 4 days to adults.

| **Labelato1a** | | | | | | | |
| 86 ± 17 | 49–85 | <36 | 4.95 ± 0.75 | 1.30 ± 0.36 | 9.11 ± 5.09 | 0.5–1.5d | 1.0 (0.86–1.2) μg/mLd |
| ↓ RDc | ↑ Childc | | | | | | |

*Active metabolite of isosorbide dinitrate. Following a 20-mg oral dose given by asymmetric dosing (0 and 7 h) for 4 days. Follows a 200-mg oral dose of labelato every 12 h for 5 doses.

| **Lamivudine** | | | | | | | |
| 97.6 ± 4.8 | 10 | 56 | 0.38–0.61d,e | 0.87–1.2 | 24–35c | 2.2 ± 1.2e | 2.5 ± 0.4 μg/mLd |
| ↓ LD; RD | ↑ LD; RD | | | | | | |

*Data from healthy adults and patients with epilepsy. Range of mean values from multiple studies reported. Lamotrigine is eliminated primarily by glucuronidation. The parent-metabolite pair may undergo enterohepatic recycling. CL/F increases slightly with multiple-dose therapy. CL/F increased and t1/2 decreased in patients receiving enzyme-inducing anticonvulsant drugs. CL/F reduced, moderate-to-severe hepatic impairment. CL/F reduced, severe RD. Following a single 200-mg oral dose to healthy adults.

</table>

<sup>a</sup>CL/F and V<sub>F</sub>/F reported. Effective t<sub>1/2</sub> to predict steady-state accumulation on multiple dosing; a terminal t<sub>1/2</sub> of 30 h reported. Following a 2.5- to 40-mg oral dose given daily to steady state in elderly patients with hypertension and varying degrees of renal function. EC_{50} for ACE inhibition is 27 ± 10 ng/mL.

*Lovastatin is an inactive lactone that is metabolized to the corresponding active β-hydroxy acid. Pharmacokinetic values are based on the sum of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibition activity by the β-hydroxy acid and other less potent metabolites.* The lactone (in equilibrium with β-hydroxy acid metabolite) is metabolized by CYP3A. Following an 80-mg oral dose given once daily for 17 days. Peak levels represent total active inhibitors (AI) and total inhibitors (TI) of HMG-CoA reductase.

*Meperidine undergoes cytochrome P450–dependent N-demethylation to normeperidine. The metabolite is not an analgesic but is a potent central nervous system–excitatory agent and is associated with adverse side effects of meperidine. *Meperidine is a weak base (pKₐ = 8.6) and is excreted to a greater extent in the urine at low urinary pH and to a lesser extent at high urinary pH. *Correlates with the concentration of α₁-acid glycoprotein.* A longer t₁/2 (7 h) also is observed. Following a continuous 24-mg/h IV infusion or 100-mg IM injection every 4 h to steady state. Postoperative analgesia occurs at 0.4–0.7 μg/mL.

*Inactive prodrug is metabolized intracellularly to 6-thiouric acid. Pharmacokinetic values for mercaptopurine are reported.* *Increases to 60% when first-pass metabolism is inhibited by allopurinol (100 mg three times daily). *Metabolically cleared by xanthine oxidase and thiopurine methyltransferase (polymorphic). Despite inhibition of intrinsic CL by allopurinol, hepatic metabolism is limited by blood flow, and CL is thus little changed by allopurinol. Following an intravenous infusion of 50 mg/m²/h to steady state in children with refractory cancers or a single oral dose of 75 mg/m² with (+) or without (–) allopurinol pretreatment.

<sup>a</sup>Data for racemic mixture reported. Metabolism of less active R (+)-enantiomer (CL/F = 28 mL/min/kg; V<sub>S</sub>/F = 7.6 L/kg; t<sub>1/2</sub> = 2.7 h) is slightly faster than that of more active S (-)-enantiomer (CL/F = 20 mL/min/kg; V<sub>S</sub>/F = 5.5 L/kg; t<sub>1/2</sub> = 3 h).<sup>b</sup>Metabolically cleared by CYP2D6 (polymorphic). Compared to extensive metabolizers (EM), individuals who are poor metabolizers (PM) have a lower CL/F and a longer t<sub>1/2</sub> (7.6 ± 1.5 vs. 2.8 ± 1.2 h) and excrete more unchanged drug in urine (15% ± 7% vs. 3.2% ± 3%) due to reduced hepatic metabolism. C<sub>L</sub>, following a single 100-mg oral dose in CYP2D6 EM and PM patients with hypertension. Plasma concentrations of the more active S-enantiomer are ~35% higher than the R-antipode in CYP2D6 EM. No stereochromical difference was observed in PM subjects. EC<sub>50</sub> for decreased systolic blood pressure during peak submaximal exercise testing was 16 ± 7 ng/mL; EC<sub>50</sub> for decreased systolic blood pressure during exercise testing was 25 ± 18 ng/mL.

APPENDIX II
DESIGN AND OPTIMIZATION OF DOSAGE REGIMENS: PHARMACOKINETIC DATA

<table>
<thead>
<tr>
<th>TABLE AII–1 ■ PHARMACOKINETIC DATA (CONTINUED)</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>BIOAVAILABILITY (ORAL) (%)</strong></td>
</tr>
<tr>
<td>Montelukasta</td>
</tr>
</tbody>
</table>

aData from healthy adult subjects. No significant gender differences. aMontelukast is metabolized by CYP3A4 and CYP2C9. CL/F is reduced by 41%, mild-to-moderate hepatic impairment with cirrhosis. Following a single 10-mg oral dose.

**Morphine**

| PO: 24 ± 12 | 4 ± 5 | 35 ± 2 | 24 ± 10 | 3.3 ± 0.9 | 1.9 ± 0.5 | IM: 0.2–0.3b | IV: 200–400 ng/mLb |
| IM: –100 | ↓ LD | ↓RD, Prem | ↓ RD | Neo, Prem | PO-IR: 0.5–1.5a | IM: –70 ng/mlb |
| PO-SR: 3–8a | PO-IR: 10 ng/mlb |

aMainly cleared by UGT2B7-dependent glucuronidation to morphine-3-glucuronide and to an active metabolite, morphine-6-glucuronide; the latter urinary excretion = 14% ± 7% and t1/2 = 4.0 ± 1.5 h. Steady-state ratio of active metabolite to parent drug after oral dosing = 4.9 ± 3.8. In renal failure, t1/2 increases to 50 ± 37 h, resulting in significant accumulation of active glucuronide metabolite. bFollowing a single 10-mg IV dose (bolus with 5-min blood sample), a 10-mg/70-kg IM, a 10-mg/70-kg immediate-release oral (PO-IR) dose, or a 50-mg sustained-release oral dose (PO-SR). Minimal analgesic concentration is 15 ng/mL.

**Moxifloxacin**

86 ± 1 | 21.9 ± 3.6 | 39.4 ± 2.4 | 2.27 ± 0.24b | 2.05 ± 1.15 | 15.4 ± 1.2 | 2.0 | (0.5–6.0)c | 2.5 ± 1.3 μg/mLc |

aData from healthy adult male and female subjects and organ transplant patients. No significant gender differences. Moxifloxacin is metabolized by CYP3A4 and CYP2C9. CL/F reported for MPA. MPAG is excreted into bile and presumably is hydrolyzed by gut flora and reabsorbed as MPA. *Accumulation of MPA and MPAG and increased unbound MPA; severe renal impairment. CL/F and Varea/F reported for MPA. Range of mean MPA CL/F and Varea/F from different studies following a 1–to-1.75-g oral dose given twice daily to steady state in renal transplant patients.

**Mycophenolate**

| MM: –0 | MPA: <1 | MPA: 97.5 | MM: 120–163 | MPA: 3.6–4c | MM: <0.033 | MPA: 1.1–2.2c | MPA: 8–19 μg/mLc |
| MPA: 94 | ↓ RD | MPA: 2.5 ± 0.4c | MPA: 16.6 ± 5.8 |
| PO-IR: 30 ± 17 | PO-IR: 30 ± 17 |

aData from healthy adult male and female subjects and organ transplant patients. No significant gender differences. Mycophenolate mofetil (MM) is rapidly converted to the active mycophenolic acid (MPA) after intravenous and oral doses. Kinetic parameters refer to MM and MPA after a dose of MM. MPA metabolized by UGT to MPA-glucuronide (MPAG). MPA undergoes enterohepatic recycling; MPAG is excreted into bile and presumably is hydrolyzed by gut flora and reabsorbed as MPA. *Accumulation of MPA and MPAG and increased unbound MPA; severe renal impairment. CL/F and Varea/F reported for MPA. Range of mean MPA CL/F and Varea/F from different studies following a 1–to-1.75-g oral dose given twice daily to steady state in renal transplant patients.

**Naltrexone**

20 ± 5 | 2 | 21 | 18.3 ± 1.4 | 16.1 ± 5.2 | 10.3 ± 3.3d | 1c | 15–64 ng/mLd |

Naltrexone has an active metabolite, 6β-naltrexol, that circulates at greater concentrations than naltrexone and has a 10-fold higher AUC than naltrexone after oral administration of naltrexone. aThe oral AUC of naltrexone was significantly increased in patients with liver impairment, whereas the AUC of 6β-naltrexol was not changed. bT1/2 of 2.7 h after intravenous administration also reported. Following a single 100-mg oral dose.

**Naproxen**

| 99a | 5–6 | 99.7 ± 0.1b | 101 ± 0.022e | 0.13 ± 0.029d, LD | 0.16 ± 0.022d | 14 ± 1 | T-IR: 2–4f | T-CR: 5f |

aData from healthy adult subjects. No significant gender differences. aEstimated bioavailability. bSaturable plasma protein binding yields apparent nonlinear elimination kinetics. cNo change in total CL, but a significant (50%) decrease in CL of unbound drug, it is thus suggested that dosing rate be decreased. A second study in elderly patients found a decreased CL and increased t1/2 with no change in percentage bound. dMetabolically cleared by CYP2C9 (polymorphic) and CYP1A2. CL/F and Varea/F reported. Following a single 250-mg dose of suspension (S) given orally to pediatric patients or a 250-mg immediate-release tablet (T-IR) or a 500-mg controlled-release tablet (T-CR) given to adults.

<sup>a</sup>Dinitrate metabolites have weak activity compared to nitroglycerin (<10%), but because of a prolonged t<sub>1/2</sub> (~40 min), they may accumulate during administration of sustained-release preparations to yield concentrations in plasma 10- to 20-fold greater than parent drug. <sup>b</sup>Following sublingual (SL) dose rinsed out of mouth after 8 min. Rinse contained 31% ± 19% of the dose. <sup>c</sup>Following a 40- to 100-min IV infusion. <sup>d</sup>IV<sub>ave</sub> reported. <sup>e</sup>Steady-state concentration following a 20- to 54-µg/min IV infusion over 40–100 min or a 0.6-mg SL dose. Levels of 1.2–11 ng/mL associated with a 25% drop in capillary wedge pressure in patients with congestive heart failure. t<sub>1/2</sub> for topical (Top) and transdermal (TD) preparations also reported.

</table>

1. Oxaliplatin is an organoplatinum complex; Pt is coordinated with diaminocyclohexane (DACH) and an oxalate ligand as a leaving group. Oxaliplatin (Ox) undergoes nonenzymatic biotransformation to reactive derivatives, notably Pt(DACH)Cl2 (PtDC). Antitumor activity and toxicity are thought to relate to the concentration of oxaliplatin and PtDC in plasma ultrafiltrate (i.e., unbound concentration). 2. For intravenous administration only: ~54% of the platinum is eliminated in urine. 3. Binding to plasma proteins is irreversible. 4. % of total platinum is much lower; ~2–4 mL/min/kg. The elimination of platinum species in plasma follows a trapezoidal pattern. The quoted $t_{1/2}$ reflects the $t_{1/2}$ of the first phase, which is the clinically relevant phase. The $t_{1/2}$ for the slower two phases are 17 and 991 h. 5. Steady-state plasma ultrafiltrate concentration of Ox and PtDC after an 85-mg/m2 IV infusion over 2 h during cycles 1 and 2.

| **Oxcarbazepine**         |                       |                     |                       |                  |                   |               |                   |
|                          |                       |                     |                       |                  |                   |               |                   |
| —                         | —                     | —                   |                       |                  |                   |               |                   |
| —                         | —                     | — 67.4              | —                     | —                | HC: 8–15         | HC: 8–15     | HC: 8.5 ± 2.0 μg/mL |

1. Data from healthy adult male subjects. No significant gender differences. Oxcarbazepine (O) undergoes extensive first-pass metabolism to an active metabolite, 10-hydroxycarbazepine (HC). Reduction by cytosolic enzymes is stereoselective (80% S-enantiomer, 20% R-enantiomer), but both show similar pharmacological activity. 2. CL/F for O reported. HC eliminated by glucuronidation. 3. AUC for HC increased, moderate-to-severe renal impairment. 4. AUC for HC decreased, children < 6 years of age. 5. Following a 300-mg oral oxcarbazepine dose given twice daily for 12 days.

| **Oxybutynin**            |                       |                     |                       |                  |                   |               |                   |
|                          |                       |                     |                       |                  |                   |               |                   |
| —                         | —                     | — 1.6–10.9          | —                     | —                | —                 | —             | IR: 5.0 ± 4.2 ng/mL |
| —                         | —                     | —                   | —                     | —                | —                 | —             | IR: 12.4 ± 4.1 ng/mL |

1. Data from healthy female subjects. No significant gender differences. Racemic mixture, anticholinergic activity resides predominantly with R-enantiomer, no stereoselectivity exhibited for anti-spasmodic activity. Oxybutynin undergoes extensive first-pass metabolism to N-desethyloxybutynin (DEO), an active, anticholinergic metabolite. Metabolized primarily by intestinal and hepatic CYP3A. Racemic oxybutynin kinetic parameters reported. 2. Data reported for a 1-mg IV dose, assuming a 70-kg body weight. A larger volume (2.8 L/kg) and longer $t_{1/2}$ (5.3 h) reported for a 5-mg IV dose. 3. Exhibits a longer apparent $t_{1/2}$ following oral dosing due to absorption rate-limited kinetics: immediate-release (IR) 4. $t_{1/2}$ for DEO was 4.0 ± 1.4 h and 8.3 ± 2.5 h for the IR and XL formulations, respectively. 5. Following a dose of 5-mg IR given three times daily or 15-mg XL given once daily for 4 days. Peak DEO levels at steady state were 45 and 23 ng/mL for IR and XL, respectively.

| **Oxycodone**             |                       |                     |                       |                  |                   |               |                   |
|                          |                       |                     |                       |                  |                   |               |                   |
| —                         | —                     | — 60–87             | —                     | —                | IR: 42 ± 7 ng/mL |

1. Oxycodone is metabolized primarily by CYP1A2/3, with a minor contribution from CYP2D6. Oxymorphone is an active metabolite produced by CYP2D6-mediated O-dealkylation. The circulating concentrations of oxymorphone are too low to contribute significantly to the opioid effects of oxycodone. Data from healthy male and female subjects reported. 2. Values reported for OXYCONTIN (oxycodone controlled-release CR) and immediate-release (IR) tablets. 3. Up to 19% excreted unchanged after an oral dose. 4. The apparent $t_{1/2}$ for the CR formulation is ~5 h; this most likely reflects absorption-limited terminal elimination kinetics. 5. Following 18 mg of OXYCONTIN (CR) given twice daily to steady state or a 5-mg IR tablet given every 6 h to steady state.

| **Paclitaxel**            |                       |                     |                       |                  |                   |               |                   |
|                          | —                     | —                   | —                     | —                | —                 | —             | 0.85 ± 0.21 pM4 |

1. Binding of drug to dialysis filtration devices may lead to overestimation of protein binding fraction (88% suggested). 2. Metabolized by CYP2C8 and CYP3A, and substrate for P-glycoprotein. 3. Average accumulation $t_{1/2}$ longer terminal $t_{1/2}$ up to 50 h are reported. 4. Steady-state concentration during a 250-mg/m2 IV infusion given over 24 h to adult cancer patients.

<sup>a</sup>Paliperidone, otherwise known as the 9-hydroxy active metabolite of risperidone, is marketed as an oral extended-release (ER) tablet (Invega) or in the form of its water-insoluble palmitate ester as a once-monthly long-acting IM injection (Invega Sustenna). Paliperidone is a racemate; its enantiomers have similar pharmacological profiles. The (+)- and (-)-enantiomers of paliperidone interconvert, reaching an AUC (+) to (–) ratio of ~ 1.6 at steady state.<sup>b</sup>High-fat/high-caloric meal increased C<sub>max</sub> and AUC by 60% and 54%, respectively. <sup>c</sup>No data on the absolute bioavailability of IM paliperidone palmitate (IM PP). The initiation regimen for Invega Sustenna (234 mg/156 mg in the deltoid muscle on day 1/day 8) produces paliperidone concentrations matching the range observed with 6- to 12-mg oral ER paliperidone. <sup>d</sup>At steady-state during once-daily doses of 3 mg, assuming an average body weight of 73 kg. <sup>e</sup>V<sub>1/2</sub> is estimated from CL/F and t<sub>1/2</sub><sup>z</sup>. <sup>f</sup>Patients with moderate hepatic impairment showed a modest increase in clearance and plasma free fraction with no significant change in unbound AUC. The apparent long terminal t<sub>1/2</sub> of paliperidone following IM depot injection reflects the slow dissolution of paliperidone palmitate and release of active paliperidone.

| **Pantoprazole**<sup>a</sup> |                      |                     |                      |                 |                 |              |                  |
| 77 (67–89)                  | □<sup>b</sup>        | 98                  | 2.8 ± 0.9            | 0.17 ± 0.04     | 1.1 ± 0.4       | 2.6 ± 0.9    | 2.5 ± 0.7 μg/mL<sup>c</sup> |
| □ LD                       | ↑ LD<sup>g</sup>     |                     |                      |                 |                 |              |                  |

<sup>a</sup>Pantoprazole is available as a racemic mixture of (+) and (-) isomers. Pantoprazole is cleared primarily by CYP2C19 (polymorphic)–dependent metabolism. Poor metabolizers (PM) exhibit profound differences in CL (lower) and t<sub>1/2</sub><sup>z</sup> (higher) compared to extensive metabolizers (EM). In CYP2C19 EM, no significant differences in the pharmacokinetics of (+) and (-) pantoprazole were observed, whereas in CYP2C19 PM, the CL of (-) pantoprazole was significantly greater than that of (+) pantoprazole. <sup>b</sup>No unchanged drug recovered in urine. Following a single 40-mg oral dose.

| **Paroxetine**<sup>a</sup> |                      |                     |                      |                 |                 |              |                  |

|                          |                     | 90 ± 25<sup>g</sup> |                      | □ LD, Aged<sup>f</sup> | 5.2 ± 0.5<sup>e</sup> | 220 nM<sup>e</sup> |

<sup>a</sup>Metabolized by CYP2D6 (polymorphic); undergoes time- and dose-dependent autoinhibition of metabolic CL in extensive metabolizers (EM).<sup>b</sup>CL/F reported for multiple dosing in EM. Single-dose data are significantly higher. In CYP2D6 poor metabolizers (PM), CL/F = 5.0 ± 2.1 mL/min/kg for multiple dosing. <sup>c</sup>V<sub>1/2</sub><sup>z</sup>/F reported. Data reported for multiple dose in EM. In PM, t<sub>1/2</sub><sup>z</sup> = 41 ± 8 h. <sup>d</sup>Estimated mean C<sub>max</sub> following a 30-mg oral dose given once daily for 14 days to adults phenotyped as CYP2D6 EM and PM. There is a significant disproportionarional accumulation of drug in blood when going from single to multiple dosing due to autoinactvation of CYP2D6.<sup>e</sup>EM: ~220 nM<sup>e</sup>.

| **Phenobarbital** |                      |                     |                      |                 |                 |              |                  |
| 100 ± 11          | 24 ± 5<sup>a</sup>  | 51 ± 3              | 0.062 ± 0.013       | 0.54 ± 0.03     | 99 ± 18         | 2–4<sup>b</sup> | 13.1 ± 4.5 μg/mL<sup>c</sup> |
| □ Neo             | ↑ Preg, Child, Neo<sup>c</sup> | ↑ Neo | ↑ LD, Aged<sup>f</sup> | ↑ Child |

<sup>a</sup>Phenobarbital is a weak acid (pK<sub>a</sub> = 7.3); urinary excretion is increased at an alkaline pH; it also is reduced with decreased urine flow. <sup>b</sup>Mean steady-state concentration following a 90-mg oral dose given daily for 12 weeks to patients with epilepsy. Levels of 10–25 μg/mL provide control of tonic-clonic seizures, and levels of at least 15 μg/mL provide control of febrile convulsions in children. Levels > 40 μg/mL can cause toxicity; 65–117 μg/mL produce stage III anesthesia—comatose but reflexes present; 100–134 μg/mL produce stage IV anesthesia—no deep-tendon reflexes.

</table>

<sup>*</sup>Metabolized predominantly by CYP2C9 (polymorphic) and also by CYP2C19 (polymorphic); exhibits saturable kinetics with therapeutic doses. Significantly decreased in the Japanese population. Comparison of CL<sub>F</sub> and t<sub>1/2</sub> with similar doses in normal subjects and patients; nonlinear kinetics not considered. <sup>4</sup>V<sub>max</sub> reported. <sup>2</sup>Apparent t<sub>1/2</sub> dependent on plasma concentration. Population frequency of total phenytoin concentrations following a 300-mg oral dose (capsule) given daily to steady state. Levels > 10 μg/mL associated with suppression of tonic-clonic seizures. Nystagmus can occur at levels > 20 μg/mL and ataxia at levels > 30 μg/mL.

**Pioglitazone**<sup>*</sup>

<sup>*</sup>Data from healthy male and female subjects and patients with type 2 diabetes. Pioglitazone (P) is metabolized extensively by CYP2C8, CYP3A4, and other CYP isozymes. Two major metabolites (M-III and M-IV) accumulate in blood and contribute to the pharmacological effect. <sup>4</sup>CL<sub>F</sub> and V<sub>max</sub>/F reported. <sup>2</sup>CL<sub>F</sub> is lower in women than in men. Steady-state t<sub>1/2</sub> of M-III and M-IV is 29 and 27 h, respectively. Following a 45-μg oral dose given once daily for 10 days.

**Posaconazole**

<sup>−</sup>66% of an oral posaconazole dose is excreted unchanged in feces. It is unclear whether this represents significant biliary excretion or unabsorbed dose. <sup>4</sup>CL<sub>F</sub>/V<sub>max</sub>/F reported. Following a single 400-mg dose of an oral suspension.

**Pramipexole**<sup>*</sup>

<sup>*</sup>Data from healthy adult male and female subjects. No significant gender differences. <sup>4</sup>Bioavailability estimated from urinary recovery of unchanged drug. <sup>4</sup>CL<sub>F</sub> and V<sub>max</sub>/F reported. <sup>2</sup>CL<sub>F</sub> reduced, moderate-to-severe renal impairment. <sup>2</sup>Parkinson’s disease (PD); CL<sub>F</sub> reduced with declining renal function. Following a 0.5-mg oral dose given three times daily for 4 days to male (M) and female (F) adults.

**Pramlintide**

<sup>3</sup>Pramlintide is a synthetic peptide analogue of amylin for the treatment of both type 1 and type 2 diabetes. It is metabolized in the kidneys to at least one primary active metabolite: Des-lys(1)pramlintide (2–37 pramlintide) with a <sup>1/2</sup> similar to that of the parent drug. <sup>4</sup>SC administration with greater variability in response when the injection is into the arm compared to into the abdomen or thigh. Not extensively bound to blood cells or albumin. Based on intravenous infusion of a low dose of 30 μg for type 1 diabetes and a high dose of 100 μg for type 2 diabetes. Following a low SC dose of 30 μg and a high SC dose of 100 μg.

</tbody>
</table>

*Although renal CL decreases with reduced renal function, no significant changes in CL/F or t½ are seen following oral dosing as a result of the low and highly variable bioavailability. A longer t½ = 1.8 ± 0.8 h reported for oral dosing, probably rate limited by absorption. Range of mean values from different studies following a single 20–mg oral dose.

**Praziquantel**

Data from male and female patients with schistosomiasis. Absolute bioavailability is not known. Praziquantel is well absorbed (80%) but undergoes significant first-pass metabolism (hydroxylation), the extent of which appears to be dose dependent. CL/F and t½ reported. CL/F and t½ are dose dependent. CL/F reduced, moderate-to-severe hepatic impairment. Range of mean values from different studies following a single 40– to 60-mg/kg oral dose.

**Prednisolone**

Prednisolone and prednisone are interconvertible, an additional 3% ± 2% is excreted as prednisone. Extent of binding to plasma proteins is dependent on concentration over range encountered. Total CL increases as protein binding is saturated. CL of unbound drug increases slightly but significantly with increasing dose. Changes are for unbound drug. V increases with dose due to saturable protein binding. Following a 30-mg oral dose given twice daily for 3 days to healthy adult male subjects. The ratio of prednisolone/prednisone is dose dependent and can vary from 3 to 26 over a prednisolone concentration range of 50–800 ng/mL.

**Prednisone**

Measured relative to equivalent intravenous dose of prednisone (PL). Additional 15% ± 5% excreted as PL. In contrast to PL, there is no dependence on concentration. Kinetic values for prednisone (P) often are reported in terms of values for PL, its active metabolite. However, the values cited here pertain to P. Range of mean data for P and PL following a single 10-mg oral dose given as different proprietary formulations to healthy adults.

**Pregabalin**

Bioavailability does not vary with dose up to 600 mg. T½ is delayed from 1 to 3 h and Cmax decreased by 25%–30% when pregabalin is given with food. No change in AUC or extent of absorption is noted. Pregabalin undergoes minimal metabolism; an N-methylated metabolite has been identified in urine and accounts for 0.9% of oral dose. Mean renal clearance in healthy young subjects ranges from 67 to 81 mL/min and assuming 70-kg body weight. Pregabalin pharmacokinetics is dose independent and predictable from single to multiple dosing. Pregabalin clearance is proportional to CLcr; hence, dosage can be adjusted in accordance to CLcr in renal dysfunction. Plasma pregabalin decreased by ~50% after 4 h of hemodialysis. Steady-state concentration in healthy subjects receiving 200-mg pregabalin every 8 h.

<sup>a</sup>Active metabolite, N-acetylprocainamide (NAPA); CL = 3.1 ± 0.4 mL/min/kg. V<sub>F</sub> = 1.4 ± 0.2 L/kg, and t<sub>1/2</sub> = 6.0 ± 0.2 h. CL<sub>cr</sub> calculated using units of mL/min/kg for CL<sub>cr</sub>. CL depends on NAT2 acetylation phenotype. Use a mean value of 2.2 if phenotype unknown. cRecovery of unchanged drug following an oral dose; the recovery of pyrazinoic acid is 37 ± 5%. dRange of mean values from different studies following a single 60-mg immediate-release tablet or syrup (IR) or 120-mg controlled-release capsule (CR) oral dose given to healthy adults. Plasma accumulation factor was 3.6-fold after 80 mg was given four times daily to steady state. A concentration of 20 ng/mL gave a 50% decrease in area of a number of inflammatory conditions. cBased on blood measurements; blood-to-plasma concentration ratio = 0.89 ± 0.03. dCYP2D6 catalyzes the formation of HP; CYP1A2 catalyzes the major conjugation pathway of elimination. eConcentration producing anesthesia after infusion to steady state (SS) and at emergence (E) from anesthesia.

### Propofol<sup>a</sup>

| 26 ± 10 | 87 ± 6<sup>c</sup> | 16 ± 5<sup>d</sup> | 4.3 ± 0.6 | 3.9 ± 0.4<sup>c</sup> | P: 1.5<sup>e</sup> | P: 49 ± 8 ng/mL<sup>e</sup> |

<sup>a</sup>Active metabolite, 4-hydroxypropranolol (HP). *Data from patients undergoing elective surgery and healthy volunteers. Propofol is extensively metabolized by UGTS. For intravenous administration only. Fraction bound in whole blood. Concentration dependent. 98.8% at 0.5 μg/mL and 98.1 ± 0.2 % at 32 μg/mL. CL and central volume increased in children 1–3 years of age. CL and central volume decreased in elderly patients. V<sub>SS</sub> is much larger than V<sub>P</sub>. A much longer terminal t<sub>1/2</sub> was reported following prolonged intravenous infusion. Concentration producing anesthesia after infusion to steady state.

### Pseudoephedrine<sup>a</sup>

| –100 | 43–96<sup>c</sup> | 7.33<sup>c</sup> | 2.64–3.51<sup>c</sup> | 4.3–8<sup>c</sup> | IR: 1.4–2<sup>d</sup> | CR: 3.8–6.1<sup>d</sup> | CR: 265–314 ng/mL<sup>e</sup> |

<sup>a</sup>Racemic mixture. For S(-)-enantiomer (100-fold more active) compared to R (+)-enantiomer, CL is 19% lower and V<sub>SS</sub> is 15% lower because of a higher degree of protein binding (18% lower free fraction); hence, there is no difference in t<sub>1/2</sub>. Active metabolite, 4-hydroxypropranolol (HP). *Drug is bound primarily to α1-acid glycoprotein, which is elevated in patients with cirrhosis.

### Pyrazinamide<sup>a</sup>

| –1<sup>b</sup> | 4–14<sup>c</sup> | 10 | 1.1 (0.2–2.3)<sup>d</sup> | 0.57 (0.13–1.04)<sup>e</sup> | 6 (2–23) | 1–2<sup>e</sup> | 35 (19–103) μg/mL<sup>e</sup> |

<sup>a</sup>Pyrazinamide is hydrolyzed in the liver to an active metabolite, 2-pyrazinoic acid. Reported peak 2-pyrazinoic acid concentrations range from 0.1- to 1-fold that of the parent drug. Pyrazinamide data reported are for male and female adults with tuberculosis. *Absolute bioavailability is not known, but the drug is well absorbed based on recovery of parent drug and metabolites (70%). *Recovery of unchanged drug following an oral dose; the recovery of pyrazinamide is 37 ± 5%. CL/F and V<sub>SS</sub>/F reported. *Following a 15–53-mg/kg daily oral dose to steady state.

| **Raloxifene**<sup>a</sup> | <0.2 | >95 | 735 ± 338<sup>b</sup> | 2348 ± 1220<sup>c</sup> | 28 (11–273) | 6<sup>d</sup> | 0.5 ± 0.3 ng/mL<sup>e</sup> |
| | ↓ LD |

| **Raltegravir** | ≥31.8 ± 9.4<sup>a</sup> | 8.8 ± 4.7 | 83 | 16.1 (11.4, 22.6)<sup>b</sup> | – | α: 0.92 ± 0.21<sup>d</sup> | 1.8<sup>e</sup> | 4.5 (2.0, 10.2) μM<sup>f</sup> |
| | β: 12.5 ± 4.6<sup>i</sup> |

<sup>a</sup>The absolute oral bioavailability of raltegravir has not been determined. This minimum extent of oral absorption is based on recovery of radioactivity in urine following oral administration of 14C-labeled raltegravir in healthy human subjects. <sup>b</sup>Raltegravir undergoes O-glucuronidation mediated largely by UGT1A1 and to a lesser extent by UGT1A3 and UGT1A9. Raltegravir AUC is only modestly elevated in individuals with UGT1A1/*28/*28 genotype compared to *1/*1 genotype. <sup>c</sup>Geometric mean (95% confidence interval) of pharmacokinetic parameters following a single 400-mg oral dose. Apparent oral clearance (CL/F) is listed. <sup>d</sup>Plasma concentration time course of raltegravir exhibits multiaistic washout kinetics. Initial (a) and terminal (β) t<sub>1/2</sub>s are reported because the early phase accounts for a large portion of the AUC from time 0 to ∞. Median for t<sub>1/2</sub>. <sup>e</sup>Correlates with serum α1-acid glycoprotein levels. Binding is increased in severe malaria. <sup>f</sup>Correlates with serum α1-acid glycoprotein levels. Binding is increased in severe malaria. References: Drugs@FDA. Isentress label approved on July 8, 2009. Available at: http://www.accessdata.fda.gov/scripts/cder/DrugsatFDA/. <sup>a</sup>Ramelteon undergoes primary oxidative metabolism followed by glucuronidation as secondary metabolism. CYP1A2 is the major enzyme involved in oxidative metabolism; CYP3A and CYP2C9 also are involved as minor enzymes. Remarkable elevation in C<sub>max</sub> and AUC were observed with the concurrent administration of the strong CYP1A2 inhibitor fluvoxamine. The M-II metabolite contributes to the hypnotic effects of ramelteon. M-II has 1/5th to 1/10th the affinity of ramelteon as an agonist for the melatonin receptors (MT-1 and MT-2); however, it circulates at 20- to 100-fold higher concentrations relative to ramelteon.<sup>a</sup>Poor systemic availability of ramelteon is due to extensive first-pass metabolism. C<sub>max</sub> and AUC are elevated by a high-fat meal; T<sub>max</sub> is slightly delayed. Calculated assuming 70-kg body weight. Although note shown, interindividual variability is notably large. Four- and 10-fold elevation in AUC in mild and moderate hepatic impairment. P = parent drug; M = M-II metabolite. C<sub>max</sub> following a single 16-mg oral dose of ramelteon in young adult subjects. There is no measurable accumulation of parent drug or active metabolite because of their short elimination t<sub>1/2</sub>.

<sup>a</sup>Hydrolyzed to its active metabolite, ramiprilat (RT). Pharmacokinetic data for ramipril (R) and RT following oral and intravenous R administration are presented. Based on plasma AUC of R and RT after intravenous and oral R administration. Following an oral dose of R, CL/F of R calculated from reported AUC data. No data available; mean renal CL of RT is ~1.1 mL/min/kg. t<sub>1/2</sub> for the elimination phase reported. A longer terminal t<sub>1/2</sub> of ~120 h most likely corresponds to the release of drug from ACE; contributes to the duration of effect but does not contribute to systemic drug accumulation. Following a single 10-mg oral dose.

*Data from healthy adult male subjects. *aUndergoes extensive oxidative and conjugative metabolism. CYP2C8 and CYP3A4 to a minor degree have been implicated in the metabolism of repaglinide. Repaglinide is also a substrate of organic anion transport protein (OATP)1B1, which is believed to contribute to the hepatic uptake of repaglinide. *bCL/F reduced, moderate-to-severe LD. *cFollowing a single 600-mg oral dose (tablet).

### APPENDIX II

#### DESIGN AND OPTIMIZATION OF DOSAGE REGIMENS: PHARMACOKINETIC DATA

*The active metabolite, 9-hydroxyrisperidone, is the predominant circulating species in extensive metabolizers and is equipotent to parent drug. 9-Hydroxyrisperidone has a t1/2 of 20 ± 3.5 h. In extensive metabolizers, 35% ± 7% of an intravenous dose is excreted as this metabolite; its elimination is primarily renal and therefore correlates with renal function.

Formation of 9-hydroxyrisperidone is catalyzed by CYP2D6. *Parameters reported for extensive metabolizers. In poor metabolizers, F is higher; ~ 20% of an intravenous dose is excreted unchanged. CL is slightly < 1 mL/min/kg, and t1/2 is similar to that of the active metabolite, ~ 20 h. ~ 77% for 9-hydroxyrisperidone.

*Changes in elderly subjects due to decreased renal function affecting the elimination of the active metabolite. *Mean steady-state Cmax for risperidone (R) and total active (TA) drug, risperidone + 9-OH-risperidone, following a 3-mg oral dose given twice daily to patients with chronic schizophrenia. No difference in total active drug levels between CYP2D6 extensive and poor metabolizers.

*Absolute bioavailability unknown (~60% absorbed); food elicits a 15% increase in oral AUC for capsule formulation. *Ritonavir is extensively metabolized primarily by CYP3A4. It also appears to induce its own CL with single-dose (SD) to multiple-dose (MD) administration. *CL/F, Vd/F, and t1/2 reported for oral dose. *CL/F reduced slightly and t1/2 increased slightly, moderate liver impairment. *Following a 600-mg oral dose given twice daily to steady state.

*Sofosbuvir is sequentially metabolized to a pharmacologically active nuclease analogue triphosphate; the active metabolite is undetected in plasma. The first hydrolytic step appears to be rapid (much of it may occur during first pass), yielding the intermediate metabolite GS-566500, which can either be fully activated by kinases to GS-461203 or inactivated by phosphatase activity to GS-331007. The absolute oral bioavailability of sofosbuvir in humans is not known. Administration with a high-fat meal increases systemic sofosbuvir exposure by 67%–91%, although this fraction is not thought to be clinically meaningful. 3.5% of the oral dose is recovered as unchanged sofosbuvir in urine; the true fraction excreted unchanged may be much higher, depending on the absolute bioavailability. (Also reported to be 62%–65% based on in vitro ultrafiltration experiments.) Mean (25th and 75th quartiles or CV%) reported following administration of 400 mg oral sofosbuvir, given once a day for 27 days. Systemic exposure (AUC) of sofosbuvir and GS-566500 increased 171% and 244%, respectively, in patients with severe renal impairment; smaller increases seen with less severe disease.

*Spironolactone (S) is extensively metabolized; it has three known active metabolites: canrenone (C), 7α-thiomethylspironolactone (TS), and 6β-hydroxy-7α-thiomethylspironolactone (HTS). Absolute bioavailability is not known, older values reported in the literature were based on nonspecific assays for C, likely to exhibit first-pass metabolism. AUC of parent drug and metabolites increased when S taken with food. Measured after an oral dose. Binding of S and its active metabolites. C<sub>1/F</sub> and V<sub>ss/F</sub> calculated from reported AUC and t<sub>1/2</sub> data. Following a single 200-mg oral dose of S. C accumulates 2.5-fold with multiple S dosing. t<sub>1/2</sub> of parent drug and metabolites increased in patients with cirrhosis.

*Temsirolimus, a water-soluble ester analogue of sirolimus or rapamycin, is available for intravenous use. Following intravenous administration, temsirolimus is converted to sirolimus; blood AUC of sirolimus is 3-fold higher than that of temsirolimus at the recommended dose of 25 mg for the treatment of advanced renal cell carcinoma. Both temsirolimus and sirolimus inhibit mTOR kinase activity and undergo oxidative metabolism mediated by CYP3A. Recovery of radioactivity after a single intravenous dose of [14C]–temsirolimus. Both temsirolimus and sirolimus partition extensively into blood cells; a major fraction of temsirolimus and sirolimus in plasma is bound to plasma proteins. Based on CL of 16.1 ± 2.5 L/h and V<sub>ss</sub> of 232 ± 36 L, at a dose of 25 mg, assuming an average body weight of 70 kg. All pharmacokinetic assessments are based on whole blood concentrations. Following the first dose of a 25-mg/week regimen.

*Tramadol (T) is available as a racemic mixture. At steady state, the plasma concentration of (+)-(1R,2R)-tramadol is ~ 30% higher than that of (-)-(1S,2S)-tramadol. Both isomers contribute to analgesia. Data reported are for total (+ and −) T. T is metabolized by CYP2D6 to an active O-desmethyl metabolite (M1); there are other CYP-catalyzed metabolites.

1 Recovery following an oral dose was reported. Following a 100-mg immediate-release tablet given every 6 h for 7 days.

PDR®. 2004, p. 2494.

*Data from healthy male and female adults. Valacyclovir is an L-valine prodrug of acyclovir. Extensive first-pass conversion by intestinal (gut wall and luminal) and hepatic enzymes. Parameters refer to acyclovir (A) and valacyclovir (V) following V administration. See Acyclovir for its systemic disposition parameters. 1 Bioavailability of A based on AUC of A following intravenous A and a 1-g oral dose of V. Uinary recovery of A is dose dependent (76% and 44% following 100-mg and 1000-mg oral doses of V and 87% following intravenous A). 1 CL/F reduced, end-stage RD (drug cleared by hemodialysis). 3 Following a single 1-g oral dose of V.

ªValganciclovir (V) is an ester prodrug for ganciclovir (G). It is rapidly hydrolyzed by a plasma t1/2 = 0.5 h. G and V data following oral V dosing as male and female patients with viral infections are reported. See Ganciclovir for its systemic disposition parameters. 1Increased and more predictable bioavailability of G when V is taken with a high-fat meal. 2The apparent t1/2 of G is increased in patients with renal impairment. 3Following a single 360 mg oral dose of V taken without food. 4Following a 900 mg oral dose of V taken once daily with food to steady state.

ªValproic acid is available either as the free acid or stable coordination compound comprised of sodium valproate and valproic acid (divalproex sodium). Systemic availability of valproate ion is the same after molar equivalent oral doses of free acid and divalproex sodium. Dose-dependent; value shown for daily doses of 250 and 500 mg. At 1 g daily, percentage bound = 90% ± 2%. 1Data for multiple dosing (500 mg daily) reported. Single-dose value: 0.14 ± 0.04 mL/min/kg; t1/2 = 9.8 ± 2.6 h. Total CL is the same at 100 mg daily, although CL of free drug increases with multiple dosing. Valproate is eliminated mainly by glucuronidation. 2Increased CL and decreased t1/2 from enzyme induction following concomitant use of other antiepileptic drugs. 3Average concentration following a 250 mg oral dose (capsule, Depakene) given twice daily for 15 days in healthy male adults. A therapeutic range of 50–150 μg/mL is reported. T1/2m is 3–8 h for divalproex tablets and 7–14 h for extended-release divalproex tablets.

<td>19.3 ± 1.7 ng/mLc</td>
<td></td>
</tr>
</tbody>
</table>

ªVardenafil is primarily metabolized by CYP3A with minor involvement of CYP2C9. The major oxidative metabolite (M1), a product of N-demethylation at the piperazine ring, is a less potent phosphodiesterase (PDE) 5 inhibitor and circulates at a level 28% of the parent drug. It contributes only 7% of the in vivo activity of vardenafil. 1V1/2 of 208 h, assuming 70-kg body weight. 2Following a single 20-mg dose. No treatment is recommended in pharmacokinetics between single and multiple dosing.

(Continued)
Verapamil

A racemic mixture; (–)-enantiomer is more active. Bioavailability of (+)-verapamil is 2.5-fold greater than that for (–)-verapamil because of a lower \( LD \) and a smaller \( \text{CL} \). Its reported \( t_{1/2} \) matches that observed for metabolite derived from \( V \). Its reported \( t_{1/2} \) in some studies, but no change of \( \tau_{ss} \) in others. \( \text{Verapamil} \) is a substrate for CYP3A4, CYP2C9, and other CYPs and for the efflux transporter P-glycoprotein.

*Venlafaxine (V) is available as a racemic mixture; antidepressant activity resides with the (–)-enantiomer and its equipotent O-desmethyl metabolite (formation catalyzed by CYP2D6–polymorphic). Parameters for the derived O-desmethylvenlafaxine (ODV) are included. ^O-Desmethyl metabolite is marketed as desvenlafaxine in an extended-release formulation as a successor to V. It has a higher oral bioavailability (80%), with a \( \tau_{ss} \) of 7.5 h. Desvenlafaxine has a much lower \( CL \) (3.5 mL/min/kg) and a smaller \( V_{ss} \) (3.4 L/kg).

*Metabolized mainly to an inactive N-oxide by CYP2C19 (major), CYP3A4, and CYP2C9. *Elimation is dose and time dependent. Pharmacokinetic parameters determined at steady state are reported. Mean CL was reduced (64%), V<sub>ss</sub> reduced (32%), and t<sub>1/2</sub> increased (16%) with 12 days of twice-daily 3-mg/kg IV administration. Also, CL decreased 41% when dose was increased from 200 to 300 mg twice daily. *CL reduced in patients with mild-to-moderate hepatic insufficiency. *Following a 3-mg/kg oral dose given twice daily for 12 days. *Following a 3-mg/kg IV infusion over 1-h given twice daily for 12 days.

**Warfarin**

| 93 ± 8 | <2 | 99 ± 6<sup>c</sup> | 0.045 ± 0.024<sup>d</sup> | 0.14 ± 0.06<sup>d</sup> | 37 ± 15<sup>c</sup> | <4<sup>d</sup> | R: 0.9 ± 0.4 µg/mL<sup>i</sup> |
| | | | | | | | S: 0.5 ± 0.2 µg/mL<sup>i</sup> |

*Values are for racemic warfarin, the S-(–)-enantiomer is 3- to 5-fold more potent than the R-(+)-enantiomer. *No difference between enantiomers in plasma protein binding or V<sub>ss</sub>, CL of the R-enantiomer is ~ 70% of that of the antipode (0.043 vs. 0.059 mL · min<sup>-1</sup> · kg<sup>-1</sup>). *Conditions leading to decreased binding (e.g., uremia) presumably increase CL and t<sub>1/2</sub>. *The S-enantiomer is metabolically cleared by CYP2C9 (polymorphic). *t<sub>1/2</sub> of the R-enantiomer is longer than that of the S-enantiomer (43 ± 14 vs. 22 ± 12 h). *Mean steady-state, 12-h postdose concentrations of warfarin enantiomers following a daily oral dose of 6.1 ± 2.3 mg of racemic warfarin given to patients with stabilized (1–5 months) anticoagulant therapy.

**Zidovudine**

| 63 ± 10 | 18 ± 5 | <25 | 26 ± 6<sup>d</sup> | 1.4 ± 0.4 | 1.1 ± 0.2 | 0.5–1<sup>c</sup> | IV: 2.6 µg/mL<sup>i</sup> |
| | | | | | | | PO: 1.6 µg/mL<sup>i</sup> |

*Formation of 5-O-glucuronide is the major route of elimination (68%). *A change in CL/F and V<sub>ss</sub>/F reported. *Following a 5-mg/kg IV or oral dose given every 4 h to steady state.

**Zonisamide**

| PO: 59 | <1<sup>e</sup> | 99.9 ± 0.08 | 11.7<sup>b</sup> | 2.3 | 2.9<sup>e</sup> | PO: 4 ± 1<sup>f</sup> | PO: 68 ± 20 ng/mL<sup>d</sup> |
| | | | | | | | IM: 0.7<sup>c</sup> |

*Recovery following oral administration. *Approximately one-third of the dose is oxidized by CYP3A4, and the remainder undergoes reduction. *A longer t<sub>1/2</sub> after oral dosing is rate limited by absorption; food decreases apparent t<sub>1/2</sub>. In the elderly, the t<sub>1/2</sub> is slightly longer. *Following a 20-mg oral dose given twice daily for 8 days. *Following a single 10-mg IM dose.

**Zolpidem**

| 72 ± 7 | <1 | 92 | 4.5 ± 0.7<sup>d</sup> | 0.68 ± 0.06 | 1.9 ± 0.2 | 1.0–2.6<sup>d</sup> | 76–139 ng/mL<sup>j</sup> |
| | | | | | | | | |

*Metabolically cleared predominantly by CYP3A4. *Following a single 10-mg oral dose given to young adults. No accumulation of drug with once-daily dosing.

**Zonisamide**

| 29–48<sup>e</sup> | 38–40<sup>e</sup> | 0.13<sup>e</sup> | 1.2–1.8<sup>f</sup> | 63 ± 14 | 1.8 ± 0.4<sup>f</sup> | 28 ± 4 µg/mL<sup>j</sup> |

*Absolute bioavailability is not known; minimum equal to urine recovery after an oral dose. *Recovery following an oral dose. *Concentrates in erythrocytes to as much as 8-fold. *Primary routes of metabolism involve reductive cleavage of the isoxazole ring (CYP3A4) and N-acetylation. *Steady-state CL/F for a 400-mg once-daily dose reported. AUC increases disproportionately when the dose is increased from 400 to 800 mg. *CL/F for a single dose is reported; decreases as the dose is increased from 20 to 800 mg. *Following a 400-mg oral dose given once daily to steady state in healthy adults.

Adenoma, pituitary, 776
Adenosine, 561, 561f, 562t, 571t, 733f
antiarhythmic actions of, 553, 558t, 560t
in autonomic neurotransmission, 145
Aminoglycosides, 962, 1039–1043, 1039b, 1040f, 1041f, 1042f, 1046f
adverse effects of, 1043–1044
for mycobacterial diseases, 1075
δ-Aminolevulinic acid (δ-ALA), 1278f
Aminopenicillins, 1024, 1029, 1036f
Aminophylline, 733–734, 746f
Aminosalicylic acid. See Para-aminosalicylic acid
Amiodarone, 31, 555, 561, 562t, 564, 564f, 571t, 1331f
adverse effects of, 552t, 564, 1265
contraindications to, 560, 561
drug-drug interactions of, 611
iodine content of, 798f
Amisulpride, 283t, 284t, 300t
Amitriptyline, 270t, 271f, 272t, 273t, 276f, 933
AML (acute myeloid leukemia), 1183, 1191, 1218f
Amlodipine, 497–498, 498f, 503t, 1331f
drug-drug interactions of, 611
for hypertension, 516, 524f
for ischemic heart disease, 495–498, 495r, 497f, 498f
for pulmonary arterial hypertension, 580f, 582, 583f
Amobarbital, 347t, 352f
Amodiaquine, 973
Amotivational syndrome, 441
Ampicillin, 207t, 271t, 271f, 272t, 273t, 276t
Ampicillin/sulbactam, 1036f
AMP (AMPK), 50f, 875, 1217f
Amphetamine, 193t, 204, 207, 220f, 235–238, 241t
adverse effects of, 204
dependence and tolerance, 204, 440
poisoning/overdose, 204
Amphotericin B, 1087–1090, 1087f, 1090f, 1090f, 1101f, 1331f
drug-drug interactions of, 454
for ophthalmic use, 1259f
for protozoal infections, 990, 996f
Ampicillin, 1029, 1036f
AMPK (AMP-activated protein kinase), 50f, 875, 1217f
Anemia
chemotherapy-associated, 755
with chloramphenicol, 1053
in chronic kidney failure, 754
folic acid for, 766
in heart failure, 543
iron deficiency, 759
perioperative, 755
with ribavirin, 1129
vitamin B12 for, 764
zidovudine-induced, 754
Anesthesia/anesthetics
general. See General anesthesia/anesthetics
local. See Local anesthesia/anesthetics
Angina. See Also ischemic heart disease

Sofosbuvir/valpatasvir, 1131–1132, 1134t
Sodium channel blockers.
Sodium fluoride, 900–901, 905t
Sodium iodide symporter (NIS), 788, 797
Sodium nitroprusside, 515, 520, 524t, 540, 544t
Sodium picosulfate, 929, 940t
Sodium polystyrene, 62
Sodium pump. See Na+/K+ ATPase (sodium
pump)
Sodium sulfadiazine, 915
Sofosbuvir/daclatasvir, 1131, 1134t
Sofosbuvir/valpatasvir, 1131–1132, 1134t
Solute carrier (SLC) superfamily. See SLC
transporter superfamily
Soma, 167t, 168, 174t
Somatic motor nerves, 115, 119–120, 119f
Somatostatin (SST), 260f, 772t, 774, 774f, 864, 883, 909
analyses, 776–777, 883, 885t, 932–933, 941t
Somatotropin family of hormones, 772, 773t.
See also specific hormones
Somatotropin, 777–778, 784t
Sonidegib, 1210, 1288
Sonidegib, 1210, 1288

Sonidegib, 1210, 1288
Sonidegib, 1210, 1288
Sonidegib, 1210, 1288
Sporotrichosis, 1089, 1090, 1093
Trypanosoma brucei gambiense. See West African trypanosomiasis
Trypanosoma brucei rhodesiense. See East African trypanosomiasis
Trypanosoma cruzi. See American trypanosomiasis (Chagas disease)
Tryptphan hydroxylase (TPH), 225
TSH (thyroid-stimulating hormone), 773, 773f, 773r, 799
Tuberculoid (paucibacillary) leprosy, 1081
Tuberculosis
antibacterial therapy for, 1043, 1045, 1067b, 1068–1079, 1069f, 1070r, 1082–1083r
definitive therapy of, 1079–1080
multidrug-resistant, 1017, 1074–1077, 1080, 1083r
prophylaxis for, 1079

U
U50,488, 358r
Ubiquinone (coenzyme Q), 974
UGT(s) (UDP-glucuronosyltransferases) in drug metabolism, 86–93, 94f
in irinotecan metabolism, 94
intrinsic clearance, 319f
expression of, 92–93, 93f, 94f
in irinotecan metabolism, 1190
UGT1A
bilirubin metabolism and, 93, 103
in drug metabolism, 92–93
in Gilbert syndrome, 93, 93f
Uric acid, 695, 702, 703f
Uric acid transporter 1 (URAT1), 66, 78f, 79, 705
Uricases, 705, 707r
Uricosuric agents, 705–706, 707r
Urokinase plasminogen activator (u-PA), 1101, 1283
Unstable angina.
Undecylenic acid, 1101, 1283
Uncompetitive inhibition, 70
Umeclidinium/vilanterol, 736, 745f
Valaciclovir, 1105–1110, 1108t, 1116t, 1293r
Vaginal dryness, 826
Valacyclovir, 1105–1110, 1108t, 1116t, 1293t
for dermatologic disorders, 1281, 1292t
for ophthalmic use, 1258r
Urapidil, 211
Urea, 446, 451–452, 451f, 1289, 1293f
Ureidopenicillins, 1029
Uric acid, 695, 702, 703f
Uric acid transporter 1 (URAT1), 66, 78f, 79, 705
Urinary acidification, 889
Urinary excretion, 1326
Urinary tract infections, 1019–1020
Urinary agents for, 1019–1020
for inflammatory bowel disease, 950, 953
Valacyclovir, 1105–1110, 1108t, 1116t, 1293t
for inflammatory bowel disease, 950, 953
